Preface to the Sixth Edition

Each edition of *Therapeutic Exercise: Foundations and Techniques* has incorporated developing trends and research in the therapeutic application of exercise. We continue this tradition in our sixth edition. This text not only provides a solid foundation in the principles and application of therapeutic exercise but also expands on this content to help the student and practitioner develop knowledge and skills in designing and implementing exercise programs that facilitate and enhance patient learning and the independence and well-being of individuals across the continuum of health.

In addition to extensive revisions and updating of content, highlights of this new edition include:

- The expanded use of highly qualified contributors. In addition to contributors for past editions of this text, who have revised or developed chapters or portions of chapters, we enlisted the assistance of several new contributors to update chapters on the spine, shoulder, knee, and lymphatic disorders. Their knowledge of current research, insights associated with their areas of specialization, and perspectives on current practice provide greater depth and breadth to this edition.
- Expansion and updating of the feature "Focus on Evidence." Research that supports exercise outcomes is emphasized.
- The addition of a new feature called "Clinical Tips." Throughout the text, hints for exercise applications are highlighted in order to enrich the reader's focus.
- Integration of the language of International Classification of Functioning, Disability and Health (ICF) with the Nagi model in order to facilitate the transition to the updated World Health Organization's health classification scheme that addresses not only impairments, activity limitations, and participation restrictions, but also health and wellness.
- The addition of spinal manipulation techniques. These interventions are now being taught in most entry-level physical therapy programs, so inclusion of principles and techniques for use in the spinal regions is a natural addition to the peripheral joint techniques.
- A new chapter on advanced functional training. Although a limited number of advanced exercises to enhance physical performance have been included in individual chapters in previous editions, it is recognized that once an individual progresses through the rehabilitation process exercises can no longer be joint specific but must incorporate integration of total body movement in order to improve functional motor skills.
- Highlighted throughout the text are links to video demonstrations of key interventions. It is recognized that visualization of the application of techniques is a useful tool for the new learner as well as the experienced therapist.

We hope our efforts with the sixth edition of this text will provide a resource for learning and professional growth of the students and healthcare practitioners who utilize therapeutic exercise.

Acknowledgments

The foundation for this edition would not exist without the mentorship and contributions of colleagues and educators who we have acknowledged in previous editions. In addition, we wish to acknowledge and express our sincere gratitude to the following educators and clinicians, who contributed their knowledge, insights, and professional perspectives to the development of this edition.

John Borstad, PT, PhD, for review and revision of portions of Chapter 17, "The Shoulder and Shoulder Girdle."

Elaine Bukowski, PT, DPT, MS, (D)ABDA Emeritus for revision of Chapter 9, "Aquatic Exercise."

John DeWitt, PT, DPT, SCS, ATC, for review and contributions to Chapter 21, "The Knee."

Karen Hock, PT, MS, CLT-LANA, for revision of Chapter 25, "Management of Lymphatic Disorders".

Karen Holtgrefe, PT, DHS, OCS, for revision of Chapter 2, "Prevention, Health, and Wellness," and Chapter 7, "Principles of Aerobic Exercise," and for revising the content on fibromyalgia, myofascial pain syndrome, and osteoporosis in Chapter 11, "Joint, Connective Tissue, and Bone Disorders and Management."

Barbara Settles Huge, PT, for her revision of Chapter 24, "Women's Health: Obstetrics and Pelvic Floor."

Anne Kloos, PT, PhD, NCS, and Deborah Givens, PT, PhD, DPT, for revision of Chapter 8, "Exercise for Impaired Balance."

Jacob Thorp, PT, DHS, MTC, for review of Chapter 14, "The Spine: Structure, Function, and Posture," and contributions to Chapter 15, "The Spine: Management Guidelines," and Chapter 16, "The Spine: Exercise and Manipulation Interventions."

A special thank you to Anne Kloos and Jacob Thorp for their assistance in setting up a portion of the photos taken at the photo shoot, to the Physical Therapy Division at The Ohio State University for use of their facility during the photo shoot, to Jason Torres of Vintage Camera Works Ltd in New York for his exceptional photography skills, and to the many individuals who modeled for the new photos and video clips.

A special thank you to Vicky Humphrey for her assistance and diligence in editing and revising the ancillary features for faculty that are associated with this edition.

A special thank you goes to Mallory Skinner, Production Editor at Graphic World, Inc., who spearheaded the copyediting and production process.

And once again, a special thank you to FA Davis staff, particularly to our Acquisitions Editor, Melissa Duffield, and to our Senior Developmental Editor, Jennifer Pine, both of whom helped bring the sixth edition to fruition.

About the Authors

Carolyn Kisner, PT, MS

Carolyn was a faculty member at The Ohio State University (OSU) for 27 years and was awarded Emeritus status after taking early retirement. During her tenure at OSU, she received the Excellence in Teaching award from the School of Allied Medical Professions and was recognized as Outstanding Faculty by the Sphinx and Mortarboard Honor Societies. She organized and managed the honors and research program for the physical therapy division, managed the advanced orthopedic track in the postprofessional graduate program, and advised numerous graduate students. Carolyn then taught at the College of Mount St. Joseph in Cincinnati for 7 years. During her tenure there, she chaired the curriculum committee, which coordinated revision of the master's program and developed the entry-level doctor of physical therapy program. She was awarded the Sister Adele Clifford Excellence in Teaching at the Mount, and at the spring convocation in 2010, she was awarded the Lifetime Achievement in Physical Therapy.

Carolyn co-authored the textbook *Therapeutic Exercise* (F.A. Davis Company) with Lynn Colby, PT, MS, first published in 1985. She and Lynn have always tried to maintain current with the trends in physical therapy, which is reflected in each of the revisions of this book; they have also co-authored the pocket-sized flip book titled *Ther Ex Notes: Clinical Pocket Guide* (F.A. Davis Company). Carolyn's primary teaching experience includes medical kinesiology, orthopedic evaluation and intervention, therapeutic exercise, and manual therapy. She has presented numerous workshops on peripheral joint mobilization, spinal stabilization, kinesiology, gait, and functional exercise nationally and internationally, including multiple visits to the Philippines, Brazil, Canada, and Mexico. Throughout her career, her active clinical involvement has been primarily in outpatient orthopedics and home health. In recognition of her achievements, Capital University in Columbus, Ohio, awarded her the Alumni Achievement Award for 2012.

Lynn Allen Colby, PT, MS

Lynn is assistant professor emeritus, The Ohio State University (OSU). She received her BS in physical therapy and MS in allied medicine from OSU, Columbus, Ohio. She is co-author of the textbook *Therapeutic Exercise: Foundations and Techniques*, now in its sixth edition, and *Ther Ex Notes: Clinical Pocket Guide*.

Recently retired, she taught in the physical therapy program in the School of Allied Medical Professions (now known as the School of Health and Rehabilitation Sciences) at OSU for 35 years. As a faculty member, she also advised physical therapists enrolled in the postprofessional graduate program in allied medicine. Her primary teaching responsibilities in the physical therapy curriculum included therapeutic exercise interventions for musculoskeletal and neurological conditions and pediatric physical therapy. Experience in the clinical setting has included acute care in orthopedics, extended care in skilled nursing facilities, and inpatient and outpatient care in various pediatric settings.

During her long career in physical therapy, she was a recipient of the Excellence in Teaching Award from the School of Allied Medical Professions at OSU and was named the Ohio Physical Therapist of the Year in 2001 by the Ohio Physical Therapy Association. Most recently, she was honored by the OSU Alumni Association with the Ralph Davenport Mershon Award for Service and Leadership.

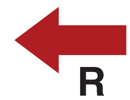
Brief Contents

Contents

Arrow Key

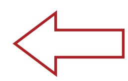
The use of arrows in the illustrations of exercise techniques in this text is purposefully designed to depict the following:

A **solid arrow with an R** indicates the direction of an external resistance force and its point of application on a segment of the body. The resistance may be an external force applied mechanically via equipment or manually by a therapist or the patient.



A **hatched arrow** indicates movement that is imposed on a segment of the patient's body by an external force. The movement may be applied to the segment as passive or active assistive range of motion, stretching, self-stretching, or mobilization techniques.

A **clear arrow** indicates active movement produced by the muscles crossing the respective joint or joints.



CHAPTER 1

Therapeutic Exercise
Foundational Concepts

Almost everyone, regardless of age, values the ability to function as independently as possible during activities of everyday life. Health-care consumers (patients and clients) typically seek out or are referred for physical therapy services because of physical impairments associated with movement disorders caused by injury, disease, or health-related conditions that restrict their ability to participate in any number of activities that are necessary or important to them. Physical therapy services may also be sought by individuals who have no impairments or functional deficits but who wish to improve their overall level of fitness and quality of life or reduce the risk of injury or disease. An individually designed therapeutic exercise program is almost always a fundamental component of the physical therapy services provided. This stands to reason because the ultimate goal of a therapeutic exercise program is the achievement of an optimal level of symptom-free movement during basic to complex physical activities.

To develop and implement effective exercise interventions, a therapist must understand how the many forms of exercise affect tissues of the body and body systems and how those exercise-induced effects have an impact on key aspects of physical function. A therapist must also integrate and apply knowledge of anatomy, physiology, kinesiology, pathology, and the behavioral sciences across the continuum of patient/client management from the initial examination to discharge planning. To develop therapeutic exercise programs that culminate in positive and meaningful functional outcomes for patients and clients, a therapist must understand the relationships among physical functioning, health, and disability and apply these conceptual relationships to patient/client management to facilitate the provision of effective and efficient health-care services. Lastly, a therapist, as a patient/client educator, must know and apply principles of motor learning and motor skill acquisition to exercise instruction and functional training.

Therefore, the purpose of this chapter is to present an overview of the scope of therapeutic exercise interventions used in physical therapy practice. This chapter also addresses several models of health, functioning, and disability as well as patient/client management as they relate to therapeutic exercise and explores strategies for teaching and progressing exercises and functional motor skills based on principles of motor learning.

Therapeutic Exercise: Impact on Physical Function

Of the many procedures used by physical therapists in the continuum of care of patients and clients, therapeutic exercise takes its place as one of the key elements that lies at the center

of programs designed to improve or restore an individual's function or to prevent dysfunction.[3]

Definition of Therapeutic Exercise

Therapeutic exercise[3] is the systematic, planned performance of bodily movements, postures, or physical activities intended to provide a patient/client with the means to:

- Remediate or prevent impairments.
- Improve, restore, or enhance physical function.
- Prevent or reduce health-related risk factors.
- Optimize overall health status, fitness, or sense of well-being.

The beneficial effects of therapeutic exercise for individuals with a wide variety of health conditions and related physical impairments are documented extensively in the scientific literature[166] and are addresssed in each of the chapters of this textbook.

Therapeutic exercise programs designed by physical therapists are *individualized* to the unique needs of each patient or client. A *patient* is an individual with impairments and functional deficits diagnosed by a physical therapist and is receiving physical therapy care to improve function and prevent disability.[3] A *client* is an individual without diagnosed dysfunction who engages in physical therapy services to promote health and wellness and to prevent dysfunction.[3] Because the focus of this textbook is on management of individuals with physical impairments and functional deficits, the authors have chosen to use the term "patient," rather than "client" or "patient/client," throughout this text. We believe that all individuals receiving physical therapy services must be active participants rather than passive recipients in the rehabilitation process to learn how to self-manage their health needs.

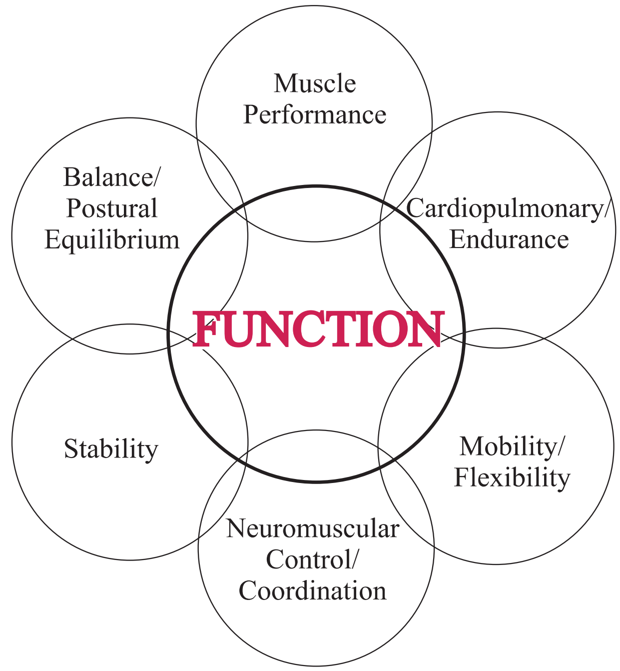


FIGURE 1.1 Interrelated components of physical function.

Components of Physical Function: Definition of Key Terms

The ability to function independently at home, in the workplace, within the community, or during leisure and recreational activities is contingent upon physical as well as psychological and social function. The multidimensional aspects of physical function encompass the diverse yet interrelated areas of performance that are depicted in Figure 1.1. These elements of function are characterized by the following definitions.

Balance. The ability to align body segments against gravity to maintain or move the body (center of mass) within the available base of support without falling; the ability to move the body in equilibrium with gravity via interaction of the sensory and motor systems.[3,85,97,114,151,154,155]

Cardiopulmonary fitness. The ability to perform moderate-intensity, repetitive, total body movements (walking, jogging, cycling, swimming) over an extended period of time.[1,105] A synonymous term is *cardiopulmonary endurance.*

Coordination. The correct timing and sequencing of muscle firing combined with the appropriate intensity of muscular contraction leading to the effective initiation, guiding, and grading of movement. Coordination is the basis of smooth, accurate, efficient movement and occurs at a conscious or automatic level.[150,154]

Flexibility. The ability to move freely, without restriction; used interchangeably with mobility.

Mobility. The ability of structures or segments of the body to move or be moved in order to allow the occurrence of range of motion (ROM) for functional activities (functional ROM).[3,161] Passive mobility is dependent on soft tissue (contractile and noncontractile) extensibility; in addition, active mobility requires neuromuscular activation.

Muscle performance. The capacity of muscle to produce tension and do physical work. Muscle performance encompasses strength, power, and muscular endurance.[3]

Neuromuscular control. Interaction of the sensory and motor systems that enables synergists, agonists and antagonists, as well as stabilizers and neutralizers to anticipate or respond to proprioceptive and kinesthetic information and, subsequently, to work in correct sequence to create coordinated movement.[92]

Postural control, postural stability, and equilibrium. Used interchangeably with static or dynamic balance.[65,151,154]

Stability. The ability of the neuromuscular system through synergistic muscle actions to hold a proximal or distal body segment in a stationary position or to control a stable base during superimposed movement.[65,154,161] Joint stability is the

maintenance of proper alignment of bony partners of a joint by means of passive and dynamic components.[111]

The systems of the body that control each of these elements of physical function react, adapt, and develop in response to forces and physical stresses (stress = force / area) placed upon tissues that make up body systems.[105,110] Gravity, for example, is a constant force that affects the musculoskeletal, neuromuscular, and circulatory systems. Additional forces, incurred during routine physical activities, help the body maintain a functional level of strength, cardiopulmonary fitness, and mobility. Imposed forces and physical stresses that are excessive can cause acute injuries, such as sprains and fractures, or chronic conditions, such as repetitive stress disorders.[110] The absence of typical forces on the body also can cause degeneration, degradation, or deformity. For example, the absence of normal weight bearing associated with prolonged bed rest or immobilization weakens muscle and bone.[1,2,12,110] Prolonged inactivity also leads to decreased efficiency of the circulatory and pulmonary systems.[1]

Impairment of any one or more of the body systems and subsequent impairment of any aspect of physical function, separately or jointly, can limit and restrict an individual's ability to carry out or participate in daily activities. Therapeutic exercise interventions involve the application of carefully graded physical stresses and forces that are imposed on impaired body systems, specific tissues, or individual structures in a controlled, progressive, safely executed manner to reduce physical impairments and improve function.

Types of Therapeutic Exercise Interventions

Therapeutic exercise procedures embody a wide variety of activities, actions, and techniques. The techniques selected for an individualized therapeutic exercise program are based on a therapist's determination of the underlying cause or causes of a patient's impairments, activity limitations, or participation restrictions (functional limitations or disability). The types of therapeutic exercise interventions presented in this textbook are listed in Box 1.1. Therapists use additional exercise interventions for patients with neuromuscular or developmental conditions.[3]

NOTE: Although joint mobilization and manipulation techniques often are categorized as manual therapy procedures, not therapeutic exercise,[3] the authors of this textbook have chosen to include joint manipulative procedures under the broad definition of therapeutic exercise to address the full scope of soft tissue stretching techniques.

Exercise Safety

Regardless of the types of therapeutic exercise interventions in a patient's exercise program, safety is a fundamental consideration in every aspect of the program whether the exercises are performed independently or under a therapist's direct supervision. Patient safety, of course, is paramount; nonetheless, the safety of the therapist also must be considered, particularly when the therapist is directly involved in the application of an exercise procedure or a manual therapy technique.

Many factors can influence a patient's safety during exercise. Prior to engaging in exercise, a patient's health history and current health status must be explored. A patient unaccustomed to physical exertion may be at risk for the occurrence of an adverse effect from exercise associated with a known or an undiagnosed health condition. Medications can adversely affect a patient's balance and coordination during exercise or cardiopulmonary response to exercise. Therefore, risk factors must be identified and weighed carefully before an exercise program is initiated. Medical clearance from a patient's physician may be indicated before beginning an exercise program.

The environment in which exercises are performed also affects patient safety. Adequate space and a proper support surface for exercise are necessary prerequisites for patient safety. If exercise equipment is used in the clinical setting or at home, to ensure patient safety, the equipment must be well maintained and in good working condition, must fit the patient, and must be applied and used properly.

Specific to each exercise in a program, the accuracy with which a patient performs an exercise affects safety, including proper posture or alignment of the body, execution of the correct movement patterns, and performance of each exercise with the appropriate intensity, speed, and duration. A patient must be informed of the signs of fatigue, the relationship of fatigue to the risk of injury, and the importance of rest for recovery during and after an exercise routine. When a patient is being directly supervised in a clinical or home setting while learning an exercise program, the therapist can control these variables. However, when a patient is carrying out an exercise program independently at home or at a community fitness facility, patient safety is enhanced and the risk of injury or re-injury is minimized by effective exercise instruction and

BOX 1.1 Therapeutic Exercise Interventions

- Aerobic conditioning and reconditioning
- Muscle performance exercises: strength, power, and endurance training
- Stretching techniques including muscle-lengthening procedures and joint mobilization/manipulation techniques
- Neuromuscular control, inhibition, and facilitation techniques and posture awareness training
- Postural control, body mechanics, and stabilization exercises
- Balance exercises and agility training
- Relaxation exercises
- Breathing exercises and ventilatory muscle training
- Task-specific functional training

patient education. Suggestions for effective exercise instruction and patient education are discussed in a later section of this chapter.

As mentioned, therapist safety also is a consideration to avoid work-related injury. For example, when a therapist is using manual resistance during an exercise designed to improve a patient's strength or is applying a stretch force manually to improve a patient's ROM, the therapist must incorporate principles of proper body mechanics and joint protection into these manual techniques to minimize his or her own risk of injury.

Throughout each of the chapters of this textbook, precautions, contraindications, and safety considerations are addressed for the management of specific health conditions/pathologies, impairments, and functional deficits and for the use and progression of specific therapeutic exercise interventions.

Classification of Health Status, Functioning, and Disability—Evolution of Models and Related Terminology

Background and Rationale for Classification Systems

Knowledge of the complex relationships among health status, functioning, and disability provides a foundation for the delivery of effective health-care services.[80,159] This knowledge, in turn, provides a theoretical framework upon which practice can be organized and research can be based, thus facilitating effective management and care of patients reflected by meaningful functional outcomes.[54,80]

Disablement, a term often used in the early health classification models,[60,67,112,113,115] refers to the impact(s) and functional consequence(s) of acute or chronic conditions, such as disease, injury, and congenital or developmental abnormalities, on specific body systems that compromise basic human performance and an individual's ability to meet necessary, customary, expected, and desired societal functions and roles.[78,112,175]

Inherent in the evolution and current application of knowledge of the disablement process in health-care delivery is an understanding that the process is *not unidirectional*—that is, it is not necessarily unpreventable or irreversible.[19] Furthermore, it is assumed that in most instances, depending on factors such as the severity and duration of the pathological condition and a patient's access to quality health care as well as the motivation and desires of the patient, the progression of the process can indeed be altered and the patient's function improved.[3,19,159,160]

An understanding and application of the disablement process shifts the focus of patient management from strict treatment of a disease or injury to treatment of the *impact* that a disease, injury, or disorder has on a patient's *function* as well as the identification of the underlying causes of the patient's dysfunction. This perspective puts the person, not solely the disease or disorder, at the center of efforts to prevent or halt the progression of disability by employing interventions that improve a patient's functional abilities while simultaneously reducing or eliminating the causes of disability.[53,159,160]

Models of Functioning and Disability—Past and Present

Early Models

Several models that depict the relationships among an individual's overall health status, functioning in everyday life, and disability have been proposed over the past four decades. The first two schema developed were the Nagi model[112,113] and the International Classification of Impairments, Disabilities, and Handicaps (ICIDH) model for the World Health Organization (WHO).[67] After publication of the original ICIDH model, it was subsequently revised,[60] with adjustments made in the descriptions of the classification criteria based on input from health-care practitioners as they became familiar with the original model. The National Center for Medical Rehabilitation Research (NCMRR) integrated components of the Nagi model with the original ICIDH model to develop its own model.[115] The NCMRR model added interactions of individual risk factors, including physical and social factors, to their classification system.

Although each of these models uses slightly different terminology, each focuses on a spectrum of disablement. Several sources in the literature have discussed, compared and contrasted, or applied the terminology and descriptors used in these and other models.[53,60,77,78,112,113,115]

Despite the variations in the early models, each taxonomy identified the following key components:

- Acute or chronic pathology
- Impairments
- Functional limitations
- Disabilities, handicaps, or societal limitations

A comparison of terminology used in the Nagi and ICIDH models is summarized in Table 1.1.

Need for a New Framework for Functioning and Disability

The conceptual frameworks of the Nagi, ICIDH, and NCMRR models, although applied widely in clinical practice and research in many health-care professions, have been criticized for their perceived focus on disease and a medical-biological view of disability as well as their lack of attention to the scope of human functioning, including wellness, and to the person with a disability.[33]

In response to these criticisms, the WHO undertook a broad revision of its conceptual framework and system for

TABLE 1.1 Comparison of Terminology of Two Disablement Models

Model	Tissue/Cellular Level	Organ/System Level	Personal Level	Societal Level
Nagi	Active pathology	Impairment	Functional limitation	Disability
ICIDH*	Disease	Impairment	Disability	Handicap

*International Classification of Impairments, Disabilities, and Handicaps

classifying disability described in its ICIDH model. Through a comprehensive consensus process over a number of years, the WHO developed the International Classification of Functioning, Disability and Health (ICF).[68,69,158-160] The ICF was designed as a companion to the WHO's International Statistical Classification of Disease and Related Health Problems (ICD), which serves as the foundation for classifying and coding medical conditions worldwide.[68,69]

The conceptual framework of the ICF (Fig. 1.2) is characterized as a bio-psycho-social model that integrates abilities and disabilities and provides a coherent perspective of various aspects of human functioning and disability as they relate to the continuum of health. The ICF also is intended to provide a common language used by all health professions for documentation and communication.[81,168]

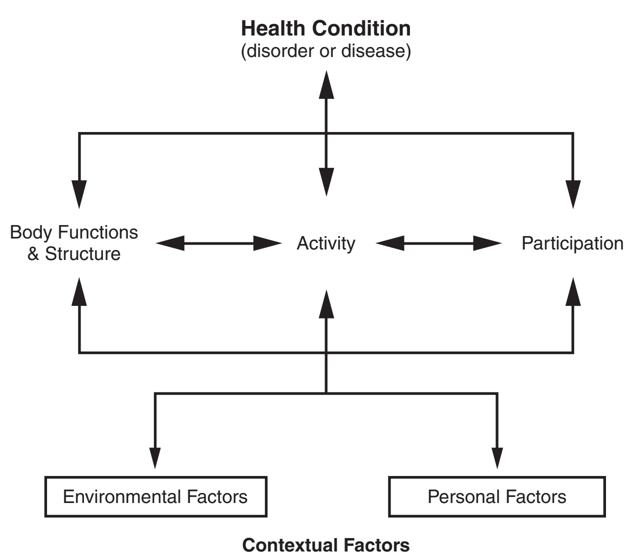

FIGURE 1.2 The ICF Framework.

The framework also was designed to place less emphasis on disease and greater emphasis on how people affected by health conditions live.[33,68,69,81,159,160] Consequently, *activity* (the execution of a task or action by an individual)[168] lies at the center of the ICF framework. All of the elements of the framework—the health condition, body functions/structures, activity, participation, and contextual factors—are interrelated and have an impact on each other.

The ICF—An Overview of the Model

The ICF is based on a broad view of health and health-related states. The model consists of two basic parts—Part 1: Functioning and Disability and Part 2: Contextual Factors as shown in Table 1.2.[68,69] Part 1 is subdivided into two components: (1) Body Functions and Structures and (2) Activities and Participation. Part 2 is also subdivided into two components: (1) Environmental Factors and (2) Personal Factors.

Functioning is characterized by the integrity of body functions and structures and the ability to participate in life's activities. In contrast, *disability* is the result of impairments in body functions and/or structures, activity limitations, and participation restrictions. Definitions of key terms are summarized in Box 1.2.[68,69,168] Numerous examples of these components are identified later in this chapter. Inclusion of contextual factors in the model highlights how external influences related to the physical environment and societal expectations and internal influences, such as personal attributes, facilitate or hinder functioning. Environmental factors that could have a positive impact on physical functioning include availability of assistive devices for personal care or household chores and modifications in the workplace or home for accessibility. Personal factors, such as level of motivation, coping skills, or acceptance of a chronic health condition, also affect daily functioning.

In addition to a conceptual model of functioning and disability, the ICF contains an extensive system for describing, classifying, and coding the functions and structures of all body systems, a person's activities and participation, as well as environmental factors that can have a positive or negative effect on functioning. The classification system, in part, provides a process for developing impairment/function-based diagnoses that guide the treatment of individuals with health conditions.

The scope of the ICF goes far beyond this brief overview of the model and related terminology presented in this chapter. To begin to understand the scope and potential use of the ICF in health care, numerous resources are available in print or online for in-depth information.[68,69,158–160]

Components of Functioning and Disability Models and Applications in Physical Therapy

Background

Traditionally, the physical therapy profession has been defined by a body of knowledge and clinical applications that are directed toward the elimination or remediation of disability.[137]

TABLE 1.2 An Overview of the *International Classification of Functioning, Disability and Health (ICF)**

	Part 1: Functioning and Disability		**Part 2: Contextual Factors**	
Components	***Body Functions and Structures***	***Activities and Participation***	***Environmental Factors***	***Personal Factors***
Domains	Body functions Body structures	Life areas (tasks, actions)	External influences on functioning and disability	Internal influences on functioning and disability
Constructs	Changes in body functions (physiological) Changes in body structures (anatomical)	*Capacity*: Executing tasks in a standard environment *Performance:* Executing tasks in the current environment	Facilitating or hindering impact of features of the physical, social, and attitudinal world	Impact of attitudes of the person
Positive aspect	Functional and structural integrity	Activities Participation	Facilitators	Not applicable
Functioning				
Negative aspect	Impairment	Activity limitation Participation restriction	Barriers Hindrances	Not applicable
Disability

BOX 1.2 Definition of Key Terms in the ICF

- **Impairments in body function:** Problems associated with of body systems (including physiological and psychological functions).
- **Impairments in body structure:** Problems with the anatomical features of the body, such as significant deviation or loss, affecting all body systems.
- **Activity limitations:** Difficulties an individual may have in executing actions, task, activities.
- **Participation restrictions:** Problems an individual may experience in involvement in life situations, including difficulties participating in self care, responsibilites in the home, workplace, or the community, and recreational, leisure and social activities.
- **Contextual factors:** The entire background of an individual's life and living situation composed of:
  - **Environmental factors:** Factors associated with the physical, social, and attitudinal environment in which people conduct their lives; factors may facilitate funcitoning (facilitators) or hinder functioning and contribure to disability (barriers).
  - **Personal factors:** Features of the individual that are not part of the health condition or health state; includes age, gender, race, lifestyle habits, coping skills, character, affect, cultural and social background, education, etc.

Understanding the disabling consequences of disease, injury, and abnormalities of development and how the risk of potential disability can be reduced, therefore, is fundamental to the provision of effective care and services, which are geared to the restoration of meaningful functioning for patients and their families, significant others, and caregivers. However, as the physical therapy profession has evolved, the scope of practice has moved beyond solely the management of disability and now includes promoting the well-being of healthy individuals and preventing or reducing risk factors that may lead to disability.

During the early 1990s, physical therapists began to explore the potential use of disablement models and suggested that disablement schema and related terminology provided an appropriate framework for clinical decision-making in practice and research.[57,77,147] In addition, practitioners and researchers suggested that consistent use of disablement-related language could be a mechanism to standardize terminology for documentation and communication in the clinical and research settings.[58] The American Physical Therapy Association (APTA) subsequently incorporated an extension of the Nagi disablement model and related terminology into its evolving consensus document, the *Guide to Physical Therapist Practice*[3] (often called the *Guide*), which was developed to reflect "best practice" from the initial examination to the outcomes of intervention. The *Guide* also uses the concept of disablement as a framework for organizing and prioritizing

clinical decisions made during the continuum of physical therapy care and services.

Just about the time the second edition of the *Guide* was published, the WHO adopted and disseminated the ICF, with its newly developed conceptual framework and system for classifying functioning and disability.[68] Consequently, information about the ICF model and its conceptual framework and terminology was not incorporated into the *Guide*. In 2008, the APTA officially endorsed the use of the ICF in physical therapy practice to increase awareness of the changing concepts and language of functioning and disability. To facilitate use of the ICF in clinical practice, a recent article in *Physical Therapy* provided a number of suggestions for integrating the ICF into specific components of the *Guide*.[40]

Since the initial publication of the ICF in 2001,[68] however, the ongoing process of integrating ICF concepts and language into physical therapy practice and the scientific literature relevant to physical therapy has been gradual but consistent. For example, use of ICF language for documentation in the clinical setting is now being advocated.[11] The most noteworthy application of the ICF can be found in a series of clinical practice guidelines developed and recently published by the Orthopedic Section of the APTA. These guidelines use the ICF as the basis for describing and classifying care provided by physical therapists to patients with selected musculoskeletal conditions.[50] Information from the guidelines addressing the efficacy of therapeutic exercise interventions for health conditions and associated impairments commonly seen in orthopedic physical therapy practice is discussed in the regional chapters of this textbook.

Regardless of which model of functioning and disability is used as part of the theoretical framework of practice, physical therapists have a responsibility to provide evidence that there are, indeed, links among the elements of functioning and disability that can be identified by physical therapy tests and measures. It is also the responsibility of the profession to demonstrate that not only can physical impairments be reduced, but functional abilities can be significantly enhanced by physical therapy interventions. Examples of evidence that is emerging are integrated into this chapter and interspersed throughout most chapters of the textbook.

In order to provide a transition from language of early disablement models to a more current language, an overview of the key components of health status, functioning, and disability contained in both the Nagi and ICF models is presented in the following sections of this chapter. In addition, a discussion of risk factors and their potential impact on functioning and disability is presented.

Health Conditions (Pathological/Pathophysiological Conditions)

Health conditions, based on the terminology of the ICF framework, are acute or chronic diseases, disorders, or injuries that have an impact on a person's level of activity (see Fig. 1.2).[68,69] The first component of the Nagi disablement model refers to such conditions as active pathology or pathological/pathophysiological conditions (see Table 1.1) that disrupt the body's homeostasis.[112,113]

Health conditions are characterized by a set of abnormal findings (clusters of signs and symptoms) that are indicative of alterations or interruptions of structure or function of the body and are primarily identified at the cellular, tissue, or organ/organ system level. Identification and classification of these abnormalities of anatomical structure or physiological process generally are the basis of a medical diagnosis and trigger medical intervention. However, it is well within a physical therapist's scope of practice using appropriate examination tools to identify abnormalities, particularly at the tissue level, that are the sources of musculoskeletal impairments.

Physical therapists in all areas of practice treat patients with a multitude of health conditions. Knowledge of the underlying pathology associated with health conditions is important background information, but it does not tell the therapist how to assess and treat a patient's impairments and subsequent dysfunction that arise from the pathological condition. Despite an accurate medical diagnosis and a therapist's thorough knowledge of specific health conditions, the experienced therapist knows full well that two patients with the same medical diagnosis, such as rheumatoid arthritis, and the same extent of joint destruction (confirmed radiologically) may have very different severities of impairment, activity (functional) limitation, and participation restriction, and, consequently, very different degrees of disability. This emphasizes the need for physical therapists to always pay close attention to the impact(s) of a particular health condition on function when designing meaningful management strategies to improve functional abilities.

Impairments

Impairments of the physiological, anatomical, and psychological functions and structures of the body are a reflection of a person's health status. Typically, impairments are the consequences of pathological conditions and encompass the signs and symptoms that reflect abnormalities at the body system, organ, or tissue level.[3,49,76]

Types of Impairment

In the ICF model, impairments are subdivided into impairments of body function and body structure. Physical therapists typically provide care and services to patients with impairments of body function and/or body structure that affect the following systems:

- Musculoskeletal
- Neuromuscular
- Cardiovascular/pulmonary
- Integumentary

Most impairments of these systems are primarily the result of acquired or congenital abnormalities of physiological function or anatomical structure. Some representative examples

of physical impairments commonly identified by physical therapists and managed with therapeutic exercise interventions are noted in Box 1.3.

Impairments of body function and body structure. Many of the impairments noted in Box 1.3, such as pain, reduced sensation, decreased ROM, deficits in muscle performance (strength, power, endurance), impaired balance or coordination, abnormal reflexes, and reduced ventilation are classified as *impairments of body function*.

Some *impairments of body structure* are readily apparent during a physical therapy examination through visual inspection. Such impairments include joint swelling, scarring, presence of an open wound, and lymphedema or amputation of a limb, or through palpation, such as adhesions, muscle spasm, and joint crepitus. Other structural impairments must be identified by a variety of imaging techniques, such as radiographic imaging to identify joint space narrowing associated with arthritis or magnetic resonance imaging (MRI) to identify a torn muscle or ligament.

Primary and secondary impairments. Impairments may arise directly from the health condition *(direct/primary impairments)* or may be the result of preexisting impairments *(indirect/secondary impairments)*. A patient, for example, who has been referred to physical therapy with a medical diagnosis of impingement syndrome or tendonitis of the rotator cuff (pathological condition) may exhibit primary impairments of body function, such as pain, limited ROM of the shoulder, and weakness of specific shoulder girdle and glenohumeral musculature during the physical therapy examination (Fig. 1.3 A&B). The patient may have developed the shoulder pathology from a preexisting postural impairment (secondary impairment), which led to altered use of the upper extremity and impingement from faulty mechanics.

BOX 1.3 Common Physical Impairments Managed with Therapeutic Exercise

Musculoskeletal

- Pain
- Muscle weakness/reduced torque production
- Decreased muscular endurance
- Limited range of motion due to:
- Restriction of the joint capsule
- Restriction of periarticular connective tissue
- Decreased muscle length
- Joint hypermobility
- Faulty posture
- Muscle length/strength imbalances

Neuromuscular

- Pain
- Impaired balance, postural stability, or control
- Incoordination, faulty timing
- Delayed motor development
- Abnormal tone (hypotonia, hypertonia, dystonia)
- Ineffective/inefficient functional movement strategies

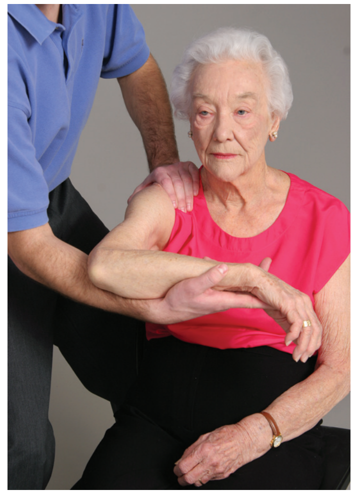
Cardiovascular/Pulmonary

- Decreased aerobic capacity (cardiopulmonary endurance)
- Impaired circulation (lymphatic, venous, arterial)
- Pain with sustained physical activity (intermittent claudication)

Integumentary

- Skin hypomobility (e.g., immobile or adherent scarring)

A



B

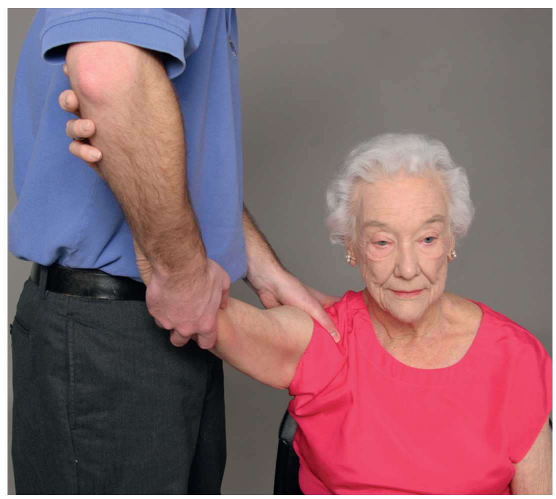


FIGURE 1.3 (A) Impingement syndrome of the shoulder and associated tendonitis of the rotator cuff (health condition/pathology) leading to **(B)** limited range of shoulder elevation (impairment of body function) are identified during the examination.

Composite impairments. When an impairment is the result of multiple underlying causes and arises from a combination of primary or secondary impairments, the term *composite impairment* is sometimes used. For example, a patient who sustained a severe inversion sprain of the ankle resulting in a tear of the talofibular ligament and whose ankle was immobilized for several weeks is likely to exhibit a balance impairment of the involved lower extremity after the immobilizer is removed. This composite impairment could be the

result of chronic ligamentous laxity (structural impairment) and impaired ankle proprioception from the injury or muscle weakness (functional impairments) due to immobilization and disuse.

Regardless of the types of physical impairment exhibited by a patient, a therapist must keep in mind that impairments manifest differently from one patient to another. Although impairments are often associated with difficulties with some daily living tasks, not all impairments are necessarily linked to activity limitations (functional limitations) and participation restrictions or lead to disability. An important key to effective management of a patient's problems is to recognize *functionally relevant impairments,* in other words, impairments that directly contribute to current or future limitations and restrictions in a patient's daily life. Impairments that can predispose a patient to secondary health conditions or impairments also must be identified.

Equally crucial for the effective management of a patient's dysfunction is the need to analyze and determine, or at least infer and certainly not ignore, the *underlying causes* of the identified physical impairments of body function or body structure, particularly those related to impaired movement.[144,145] For example, are biomechanical abnormalities of soft tissues the source of restricted ROM? If so, which soft tissues are restricted, and why are they restricted? This information assists the therapist in the selection of appropriate, effective therapeutic interventions that target the underlying *causes* of the impairments, the impairments themselves, and the resulting functional deficits.

Although most physical therapy interventions, including therapeutic exercise, are designed to correct or reduce physical impairments of body function, such as decreased ROM or strength, poor balance, or limited cardiopulmonary endurance, the focus of treatment ultimately must be on restoration of function and prevention or reduction of dysfunction. Elimination or reduction of functionally relevant impairments is necessary during treatment. From a patient's perspective, however, *successful outcomes* of treatment are determined by a reduction or resolution of functional deficits and the restoration or improvement of daily functioning. A therapist cannot simply assume that intervening at the impairment level (e.g., with strengthening or stretching exercises) and subsequently reducing physical impairments (by increasing strength and ROM) generalize to improvement in a patient's level of activity and restoration of functional abilities for daily living. Mechanisms for integrating correction of physical impairments and restoration of functional abilities through task-specific training are explored in a model of effective patient management presented in a later section of this chapter.

Activity Limitations/Functional Limitations

In the language of the ICF, *activity limitations* occur when a person has difficulty executing or is unable to perform tasks or actions of daily life (see Box 1.2).[33,68,69,158-160,168] *Functional limitations*, which can be considered analogous to activity limitations, are described in the Nagi disablement model (see Table 1.1) as difficulties in functioning that occur at the level of the whole person.[112,113] Nagi also suggests that they are the result of impairments associated with active pathology and are characterized by the reduced ability of a person to perform actions or components of motor tasks in an efficient or typically expected manner. For example, as shown in Figure 1.4, restricted range of motion (impairment) of the shoulder as the result of adhesive capsulitis (health disorder/pathological condition) can limit a person's ability to reach overhead (activity limitation/functional limitation) while performing personal grooming or household tasks.

FIGURE 1.4 Limited ability to reach overhead (activity limitation/functional limitation) as the result of impaired shoulder mobility may lead to loss of independence in self care and difficulty performing household tasks independently (participation restriction/disability).

Limitations in a person's functioning may be *physical, social, or psychological* in nature. The focus of physical therapy interventions is on the management of limitations of physical functioning while respecting the needs of the whole person and recognizing that social and psychological influences also can limit a person's ability to function. During the course of patient management, if physical therapy interventions are to be effective, the focus of treatment must be directed toward remediating impairments *and* activity limitations that have the greatest adverse effects on a patient's functioning during daily activities, as well as those that are most important to the patient. Impairments and activity limitations that are or could be directly restricting a patient's participation in his or her roles and responsibilities in the home or community and, therefore, contributing to disability also must be addressed. When impairments and activity limitations restrict participation, a patient's health-related *quality of life* may begin to deteriorate.

Many studies have linked activity/functional limitations with body function impairments, particularly in older adults.

Links have been identified between limited ROM of the shoulder and difficulty reaching behind the head or back while bathing and dressing,[169] between decreased isometric strength of lower extremity musculature and difficulty stooping and kneeling[63] as well as a link between decreased lower extremity peak power and reduced walking speed and difficulty moving from sitting to standing.[129] However, it should also be noted that a single or even several mild impairments of body function or structure often do not cause loss of functioning associated with activity. For example, results of a two-year observational study of patients with symptomatic hip or knee osteoarthritis (OA) demonstrated that increased joint space narrowing (a body structure impairment that is considered an indicator of progression of the disease) confirmed radiologically was not associated with an increase in activity limitations as measured on a self-report assessment of physical functioning.[18] Furthermore, evidence from other studies suggests that the severity and complexity of impairments must reach a critical level, which is different for each person, before degradation of functioning begins to occur.[122,131]

Types of Activity Limitations/Functional Limitations

Limitations in the area of physical functioning deal with the performance of sensorimotor tasks—that is, total body actions that typically are *components or elements* of functional activities. These activities include basic activities of daily living (BADL), such as bathing, dressing, or feeding, and the more complex tasks known as instrumental activities of daily living (IADL), such as occupational tasks, school-related skills, housekeeping, and recreational activities, or community mobility (driving, using public transportation), just to name a few.

Box 1.4 identifies a number of activity limitations/functional limitations that can arise from physical impairments in body function or structure, involve *whole-body movements or actions,* and are necessary component motions of simple to complex daily living tasks. Defining limitations in this way highlights the importance of identifying abnormal or absent component motions of motor skills through task analysis during the physical therapy examination and later integrating task-specific functional motions into a therapeutic exercise program.

When a person is unable or has only limited ability to perform any of the whole-body component motions identified in Box 1.4, decreased independence in BADL and IADL may occur, quality of life may become compromised, and hence, disability may ensue. The following is an example of this relationship between activity limitations and potential disability. To perform a basic home maintenance task (IADL), such as painting a room, a person must be able to grasp and hold a paintbrush or roller, climb a ladder, reach overhead, kneel, or stoop down to the floor. If any one of these component movements is limited, it may not be possible to perform the overall task of painting the room.

An essential element of a physical therapy examination and evaluation is the analysis of motor tasks to identify the component motions that are difficult for a patient to perform.

BOX 1.4 Common Activity Limitations/Functional Limitations Related to Physical Tasks

Difficulties with or limitation of:
- Reaching and grasping
- Lifting, lowering, and carrying
- Pushing and pulling
- Bending, stooping
- Turning, twisting
- Throwing, catching
- Rolling
- Sitting or standing tolerance
- Squatting (crouching) and kneeling
- Standing up and sitting down (from and to a chair, the floor)
- Getting in and out of bed
- Moving around (crawling, walking, running) in various environments
- Ascending and descending stairs
- Hopping and jumping
- Kicking or swinging an object

This analysis helps the therapist determine why a patient is unable to perform specific daily living tasks. This information coupled with identification and measurement of the impairments that are the source of the altered or absent component movement patterns, in turn, is used for treatment planning and selection of interventions to restore function and prevent potential disability.

Participation Restrictions and Disability

As identified in the ICF model (see Table 1.2), *participation restrictions* are defined as problems a person may experience in his or her involvement in life situations as measured against social standards (see Box 1.2).[68,69,158-160,168] More specifically, participation restrictions encompass problems that deal with fulfilling personal or social responsibilities and obligations in relation to societal expectations in the context of a person's attitudes and environment.

Disability is the term in the Nagi model (see Table 1.1) used to describe the inability to participate in activities or tasks related to one's self, the home, work, recreation, or the community in a manner or to the extent that the individual or the community as a whole (e.g., family, friends, coworkers) perceive as "normal."[112,113]

To add to the disparity of how terms are defined in various models, the definition of *disability* in the ICF is not limited to societal or individual functioning. Rather, it is an umbrella term that encompasses impairments of body function and/or structure, activity limitations, and participation restrictions as noted previously in the overview of the ICF model (see Table 1.2).[68,69,168]

Social expectations or roles that involve interactions with others and participation in activities are an important part of who each of us is. These roles are specific to age, gender, sex,

and cultural background. Categories of activities or roles that, if limited, may contribute to participation restrictions or disability are summarized in Box 1.5. However, it is important to point out that the description of participation restrictions in the ICF primarily focuses on limitations associated with societal functioning, whereas the description of disability in the Nagi model is inclusive of individual functioning in the context of the environment, such as personal care (BADL) and more complex daily living skills (IADL) as well as societal functioning.

Because disability is such a complex process, the extent to which each aspect of functioning or disability affects one's perceived level of disability is not clearly understood. An assumption is made that when impairments and activity limitations are so severe or of such long-duration that they cannot be overcome to a degree acceptable to an individual, a family, or society, the perception of "being disabled" occurs.[131] The perception of disability is highly dependent on a person's or society's expectations of how or by whom certain roles or tasks *should* be performed.

There is a growing body of evidence suggesting that physical impairments and activity limitations/functional limitations directly or indirectly contribute to participation restrictions or disability.[76,79,129,169] Consequently, an approach to patient management that focuses on restoring or improving a patient's level of functioning may prevent or reduce disability and may have a positive impact on quality of life.

Prevention of Disability

Understanding the relationships among a health condition, impairments, activity limitations (functional limitations), participation restrictions, and the impact of environmental and personal factors on functioning is fundamental to the prevention or reduction of disability.[19,53,78] The presence of impairments and limitations may or may not lead to loss of independence and result in disability.

Take, for example, a relatively inactive person with long-standing osteoarthritis of the knees. The inability to get up from the floor or from a low seat (activity limitation/functional limitation) because of limited flexion of the knees and power deficits of the hip and knee extensors (impairments in body function) could indeed lead to restricted participation in life's activities and disability in several areas of everyday functioning. Disability could be expressed by problems in self-care (inability to get in and out of a tub or stand up from a standard height toilet seat), home management (inability to perform selected housekeeping, gardening, or yard maintenance tasks), or community mobility (inability to get into or out of a car or van independently).

The perception of disability possibly could be minimized if the patient's functional ROM and strength can be improved with an exercise program and the increased ROM and strength are incorporated into progressively more challenging functional activities or if the physical environment can be altered sufficiently with the use of adaptive equipment and assistive devices.

Adjusting expected roles or tasks within the family might also have a positive impact on the prevention or reduction of disability. Factors within the individual also can have an impact on the prevention, reduction, or progression of disability. Those factors include level of motivation or willingness to make lifestyle changes and accommodations as well as the ability to understand and cope with an adjusted lifestyle.[175] This example highlights that inherent in any discussion of disability is the assumption that it can be prevented or remediated.[19]

Categories of prevention. Prevention falls into three categories.[3]

- **Primary prevention:** Activities such as health promotion designed to prevent disease in an at-risk population
- **Secondary prevention:** Early diagnosis and reduction of the severity or duration of existing disease and sequelae
- **Tertiary prevention:** Use of rehabilitation to reduce the degree or limit the progression of existing disability and improve multiple aspects of function in persons with chronic, irreversible health conditions

Therapeutic exercise, the most frequently implemented physical therapy intervention, has value at all three levels of prevention. For example, the use of resistance exercises and aerobic conditioning exercises in weight-bearing postures is often advocated for the primary and secondary prevention of age-related osteoporosis.[32,62] However, therapists who work with patients with chronic musculoskeletal or neuromuscular diseases or disorders routinely are involved with tertiary prevention of disability.

BOX 1.5 Areas of Functioning Associated with Participation Restrictions and Disability

- Self-care
- Mobility in the community
- Occupational tasks
- School-related tasks
- Home management (indoor and outdoor)
- Caring for dependents
- Recreational and leisure activities
- Socializing with friends/family
- Community responsibilities and service

Risk Factors

Modifying risk factors through an intervention, such as therapeutic exercise, is an important tool for preventing or reducing the impact of health conditions and subsequent impairments, limitations, and restrictions in functioning that may lead to disability. Risk factors are influences or characteristics that predispose a person to impaired functioning and potential disability. As such, they exist *prior to* the onset of a health condition and associated impairments, limitations, or

restrictions.[19,78,175] Some factors that increase the risk of disability are biological characteristics, lifestyle behaviors, psychological characteristics, and the impact of the physical and social environments. Examples of each of these types of risk factor are summarized in Box 1.6.

Some of the risk factors, in particular lifestyle characteristics and behaviors and their impact on the potential for disease or injury, have become reasonably well known because of public service announcements and distribution of educational materials in conjunction with health promotion campaigns, such as *Healthy People 2010*[172] and *Healthy People 2020*.[173] Information on the adverse influences of health-related risk factors, such as a sedentary lifestyle, obesity, and smoking, has been widely disseminated by these public health initiatives. Although the benefits of a healthy lifestyle, which includes regular exercise and physical activity, are well-founded and widely documented,[1,172,173] initial outcomes of a previous national campaign, *Healthy People 2000*,[128] suggest that an increased awareness of risk factors has not translated effectively into dramatic changes in lifestyle behaviors to reduce the risk of disease or injury.[42] This demonstrates that increased knowledge does not necessarily change behavior.

When a health condition exists, the reduction of risk factors by means of *buffers* (interventions aimed at reducing the progression of a pathological condition, impairments, limitations, restrictions, and potential disability) is appropriate.[78] This focus of intervention is categorized as secondary or tertiary prevention. Initiating a regular exercise program and increasing the level of physical activity on a daily basis or altering the physical environment by removing architectural barriers or using assistive devices for a range of daily activities are examples of buffers that can reduce the risk of disability. (Refer to Chapter 2 of this textbook for additional information on prevention, reduction of health-related risk factors, and wellness.)

BOX 1.6 Risk Factors for Disability

Biological Factors
- Age, sex, race
- Height/weight relationship
- Congenital abnormalities or disorders (e.g., skeletal deformities, neuromuscular disorders, cardiopulmonary diseases, or anomalies)
- Family history of disease; genetic predisposition

Behavioral/Psychological/Lifestyle Factors
- Sedentary lifestyle
- Cultural biases
- Use of tobacco, alcohol, other drugs
- Poor nutrition
- Low level of motivation
- Inadequate coping skills
- Difficulty dealing with change or stress
- Negative affect

Physical Environment Characteristics
- Architectural barriers in the home, community, and workplace
- Ergonomic characteristics of the home, work, or school environments

Socioeconomic Factors
- Low economic status
- Low level of education
- Inadequate access to health care
- Limited family or social support

Summary

An understanding of the concepts of functioning and disability; of the relationships among the components of functioning, disability, and health; and of the various models and classification systems that have been developed over the past four decades provides a conceptual framework for practice and research. This knowledge also establishes a foundation for sound clinical decision-making and effective communication and sets the stage for delivery of effective, efficient, meaningful physical therapy care and services for patients.

Patient Management and Clinical Decision-Making: An Interactive Relationship

An understanding of the concepts of functioning and disability coupled with knowledge of the process of making informed clinical decisions based on evidence from the scientific literature provides the foundation for comprehensive management of patients seeking and receiving physical therapy services. Provision of quality patient care involves the ability to make sound clinical judgments, solve problems that are important to a patient, and apply knowledge of the relationships among a patient's health condition(s), impairments, limitations and restrictions in daily activities, and resulting disability throughout each phase of management.

The primary purpose of this section of the chapter is to describe a model of patient management used in physical therapy practice. Inasmuch as clinical reasoning and evidence-based decision-making are embedded in each phase of patient management, a brief overview of the concepts and processes associated with clinical decision-making and evidence-based practice is presented before exploring a systematic process of patient management in physical therapy. Relevant examples of the clinical decisions a therapist must make are highlighted within the context of the patient management model.

Clinical Decision-Making

Clinical decision-making refers to a dynamic, complex process of reasoning and analytical (critical) thinking that involves making judgments and determinations in the context of ptient care.[84] One of the many areas of clinical decision-making in

which a therapist is involved is the selection, implementation, and modification of therapeutic exercise interventions based on the unique needs of each patient or client. To make effective decisions, merging clarification and understanding with critical and creative thinking is necessary.[91] A number of requisite attributes are necessary for making informed, responsible, efficient, and effective clinical decisions.[39,91,103,152] Those requirements are listed in Box 1.7.

There is a substantial body of knowledge in the literature that describes various strategies and models of clinical decision-making in the context of patient management by physical therapists.* One such model, the Hypothesis-Oriented Algorithm for Clinicians II (HOAC II), describes a series of steps involved in making informed clinical decisions.[139]

The use of clinical decision-making in the diagnostic process also has generated extensive discussion in the literature.† To assist in the decision-making process and ultimately improve patient care, tools known as *clinical prediction rules*, first developed in medicine, also have been developed for use by physical therapists.[25,44] Some clinical prediction rules (CPRs) contain predictive factors that help a clinician establish specific diagnoses or improve the accuracy of prognoses, whereas others identify subgroupings of patients within large, heterogeneous groups who are most likely to benefit from a particular approach to treatment or specific therapeutic interventions. To date, some prediction tools in physical therapy have been developed to assist in the diagnosis of health conditions, including osteoarthritis in patients with hip pain[162] and deep vein thrombosis in patients with leg pain.[134] However, a greater number of CPRs in physical therapy have been established to predict likely responses of patients to treatment. As examples, CPRs have been developed to identify a subgrouping of patients with patellofemoral pain syndrome who are most likely to respond positively to lumbopelvic manipulation,[70] patients with low back pain most likely to respond to stabilization exercises,[64] and those with neck pain for whom thoracic spine manipulation is most likely to be effective.[28]

It is important to note, however, that little research, thus far, has focused on validation of published CPRs[10] or their impact on the effectiveness of patient care from specific therapeutic interventions. The results of two recent systematic reviews of the literature underscore these points. One review[10] indicated that the quality of the studies on which CPRs to determine treatment effectiveness have been based varies considerably. The results of the other review of CPRs for musculoskeletal conditions[157] demonstrated that currently there is only limited evidence to support the use of these rules to predict the effectiveness of specific interventions or to optimize treatment. Additional information from studies directed toward clinical decision-making is integrated into the remainder of this section on patient management or is addressed in later chapters.

Health care continues to move in the direction of physical therapists being the first-contact practitioners through whom consumers gain access to services without physician referral. Hence, the need to make sound clinical judgments supported by scientific evidence during each phase of patient management has become more essential for physical therapy practitioners.

BOX 1.7 Requirements for Skilled Clinical Decision-Making During Patient Management

- Knowledge of pertinent information about the problem(s) based on the ability to collect relevant data by means of effective examination strategies
- Cognitive and psychomotor skills to obtain necessary knowledge of an unfamiliar problem
- Use of an efficient information-gathering and information-processing style
- Prior clinical experience with the same or similar problems
- Ability to recall relevant information
- Ability to integrate new and prior knowledge
- Ability to obtain, analyze, and apply high-quality evidence from the literature
- Ability to critically organize, categorize, prioritize, and synthesize information
- Ability to recognize clinical patterns
- Ability to form working hypotheses about presenting problems and how they might be solved
- Understanding of the patient's values and goals
- Ability to determine options and make strategic plans
- Application of reflective thinking and self-monitoring strategies to make necessary adjustments

Evidence-Based Practice

Physical therapists who wish to provide high-quality patient care must make informed clinical decisions based on sound clinical reasoning and knowledge of the practice of physical therapy. An understanding and application of the principles of evidence-based practice provide a foundation to guide a clinician through the decision-making process during the course of patient care.

Definition and Description of the Process

Evidence-based practice is "the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of an individual patient."[142] Evidence-based practice also involves combining knowledge of evidence from well-designed research studies with the expertise of the clinician and the values, goals, and circumstances of the patient.[143]

The process of evidence-based practice involves the following steps[29,143]:

1. Identify a patient problem and convert it into a specific question.
2. Search the literature and collect clinically relevant, scientific studies that contain evidence related to the question.

3. Critically analyze the pertinent evidence found during the literature search and make reflective judgments about the quality of the research and the applicability of the information to the identified patient problem.
4. Integrate the appraisal of the evidence with clinical expertise and experience and the patient's unique circumstances and values to make decisions.
5. Incorporate the findings and decisions into patient management.
6. Assess the outcomes of interventions and ask another question if necessary.

This process enables a practitioner to select and interpret the findings from the evaluation tools used during the examination of the patient and to implement effective treatment procedures that are rooted in sound theory and scientific evidence (rather than anecdotal evidence, opinion, or clinical tradition) to facilitate the best possible outcomes for a patient.

FOCUS ON EVIDENCE

In a survey of physical therapists, all of whom were members of the American Physical Therapy Association, 488 respondents answered questions about their beliefs, attitudes, knowledge, and behavior about evidence-based practice.[82] Results of the survey indicated that the therapists believed that the use of evidence in practice was necessary and that the quality of care for their patients was better when evidence was used to support clinical decisions. However, most thought that carrying out the steps involved in evidence-based practice was time-consuming and seemed incompatible with the demands placed on therapists in a busy clinical setting.

It is impractical to suggest that a clinician must search the literature for evidence to support each and every clinical decision that must be made. Despite time constraints in the clinical setting, when determining strategies to solve complex patient problems or when interacting with third-party payers to justify treatment, the "thinking therapist" has a professional responsibility to seek out evidence that supports the selection and use of specific evaluation and treatment procedures.[7]

Accessing Evidence

One method for staying abreast of evidence from current literature is to read one's professional journals on a regular basis. It is also important to seek out relevant evidence from high-quality studies (randomized controlled trials, systematic reviews of the literature) from journals of other professions.[30] Journal articles that contain systematic reviews of the literature or summaries of multiple systematic reviews are an efficient means to access evidence, because they provide a concise compilation and critical appraisal of a number of scientific studies on a topic of interest.

Evidence-based *clinical practice guidelines* for management of specific physical conditions or groupings of impairments also have been developed; they address the relative effectiveness of specific treatment strategies and procedures. These guidelines provide recommendations for management based on systematic reviews of current literature.[127,146] Initially, clinical practice guidelines that address four broadly defined musculoskeletal conditions commonly managed by physical therapists—specifically knee pain,[123] low back pain,[124] neck pain,[125] and shoulder pain[126]—were developed by the Philadelphia Panel, a panel of experts from physical therapy and medicine.

As mentioned previously in this chapter, a series of clinical practice guidelines has been created and recently published by the Orthopedic Section of the APTA. These guidelines provide evidence-based recommendations for orthopedic physical therapy management (diagnosis, prognosis, selection of therapeutic interventions, and use of outcome measures) of a number of impairment/function-based groupings that are based on the ICF.[50] Some examples include clinical practice guidelines for management of neck pain,[26] knee pain and mobility impairments,[94] knee stability impairments,[95] hip pain and mobility deficits associated with osteoarthritis,[27] heel pain associated with plantar fasciitis,[107] and deficits associated with Achilles tendonitis.[22] More specific information from these guidelines is integrated into the regional chapters of this textbook.

If articles that contain systematic reviews of the literature on a specific topic have not been published, a therapist may find it necessary and valuable to perform an individual literature search to identify evidence applicable to a clinical question or patient problem. Journals exclusively devoted to evidence-based practice are another means to assist the practitioner who wants to identify well-designed research studies from a variety of professional publications without doing an individual search. These journals provide abstracts of research studies that have been critically analyzed and systematically reviewed.

Online bibliographic databases also facilitate access to evidence. Many databases provide systematic reviews of the literature relevant to a variety of health professions by compiling and critiquing several research studies on a specific patient problem or therapeutic intervention.[7,29,109] One example is the Cochrane Database of Systematic Reviews, which reports peer-reviewed summaries of randomized controlled trials and the evidence for and against the use of various interventions for patient care, including therapeutic exercise. Although a recent study[108] identified CENTRAL (Cochrane Central Registry of Controlled Trials), PEDro (Physiotherapy Evidence Database), PubMed, and EMBASE (Excerpta Medica Database) as the four most comprehensive databases indexing reports of randomized clinical trials of physical therapy interventions, only PEDro exclusively reports trials, reviews, and practice guidelines pertinent to physical therapy.[99] Easily accessed online databases such as these streamline the search process and provide a wealth of information from the literature in a concise format.

To further assist therapists in retrieving and applying evidence in physical therapist practice from the Cochrane online library, the *Physical Therapy* journal publishes a recurring feature called Linking Evidence and Practice (LEAP). This feature summarizes a Cochrane review and other scientific evidence on a single topic relevant to physical therapy patient care. In addition, LEAP presents case scenarios to illustrate how the results of the review of evidence can be applied to the decision-making process during patient management.

In support of evidence-based practice, relevant research studies are highlighted or referenced throughout each of the chapters of this text in relationship to the therapeutic exercise interventions, manual therapy techniques, and management guidelines presented and discussed. However, there is also an absence of research findings to support the use of some of the interventions presented. For such procedures, a therapist must rely on clinical expertise and judgment as well as each patient's response to treatment to determine the impact of these interventions on patient outcomes. Examples of how to incorporate the ongoing process of clinical decision-making and application of evidence into each phase of patient management are presented in the following discussion of a model for patient management.

A Patient Management Model

The physical therapy profession has developed a comprehensive approach to patient management designed to guide a practitioner through a systematic series of steps and decisions for the purpose of helping a patient achieve the highest level of functioning possible. This model is illustrated in Figure 1.5.

As described in the *Guide to Physical Therapist Practice*, the process of patient management has five basic components.[3,14,46]

1. A comprehensive *examination*
2. *Evaluation* of data collected
3. Determination of a *diagnosis* based on impairments of body structure and function, functional limitations (activity limitations), and disability (participation restrictions)
4. Establishment of a *prognosis* and plan of care based on patient-oriented goals
5. Implementation of appropriate *interventions*

The patient management process culminates in the attainment of meaningful functional *outcomes* by the patient, which then must be re-examined and re-evaluated before a patient's discharge from care. As the model indicates, the *re-examination* and *re-evaluation* process occurs not only at the conclusion of treatment but throughout each phase of

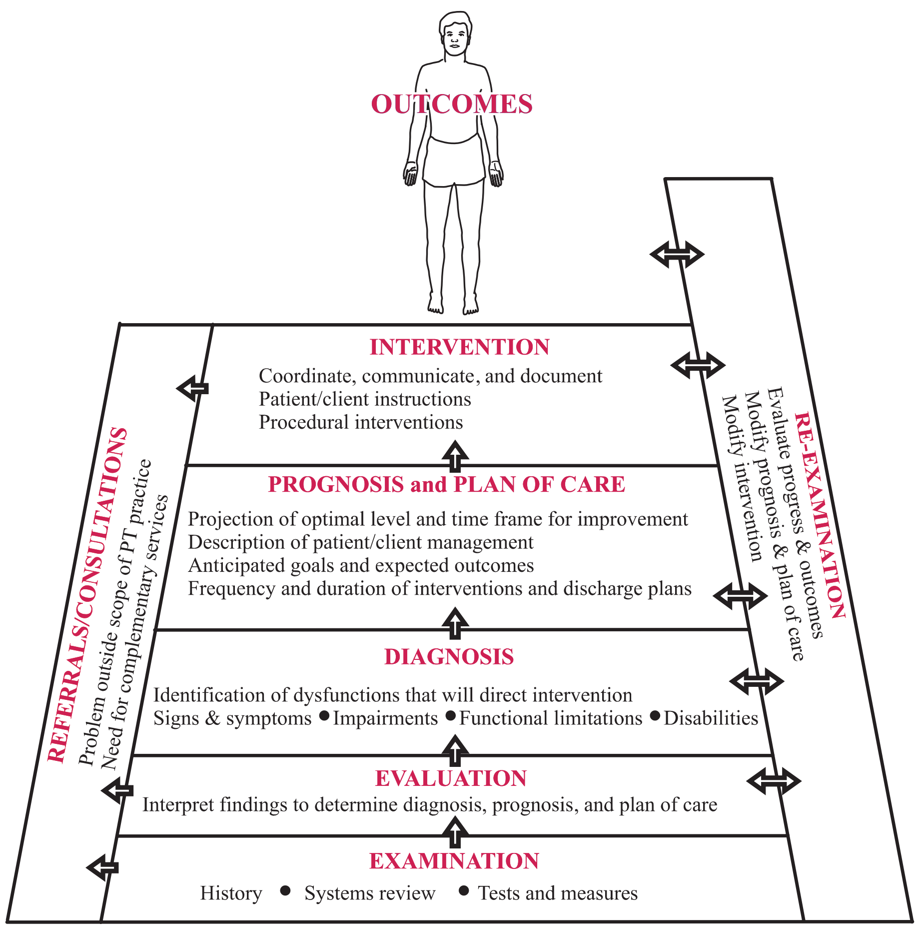

FIGURE 1.5 A comprehensive outcomes-oriented model of patient management.

patient management. The ability to make timely decisions and appropriate judgments and to develop or adjust an ongoing series of working hypotheses makes transition from one phase of management to the next occur in an effective, efficient manner.

Examination

The first component of the patient management model is a comprehensive examination of the patient. Examination is the systematic process by which a therapist obtains information about a patient's problem(s) and his or her reasons for seeking physical therapy services. During this initial data collection, the therapist acquires information from a variety of sources. The examination process involves both comprehensive screening and specific diagnostic testing. It is the means by which the therapist gathers sufficient information about the patient's existing or potential problems (health conditions, impairments, activity/functional limitations, participation restrictions/disabilities) to ultimately formulate a diagnosis and determine whether these problems can be appropriately treated by physical therapy interventions. If treatment of the identified problems does not fall within the scope of physical therapy practice, referral to another health-care practitioner or resource is warranted. The examination is also the means by which baseline measurements of current impairments, functional deficits and abilities are established as a reference point from which the results of therapeutic interventions can be measured and documented.

There are three distinct elements of a comprehensive examination.[3]

- The patient's health history
- A relevant systems review
- Specific tests and measures

Throughout the examination process, a therapist seeks answers to an array of questions and concurrently makes a series of clinical decisions that shape and guide the examination process. Examples of some questions to be asked and decisions to be made are noted in Box 1.8.

History

The history is the mechanism by which a therapist obtains an *overview* of current and past information (both subjective and objective) about a patient's present condition(s), general health status (health risk factors and coexisting health problems), and why the patient has sought physical therapy services. It has been shown in a multi-center study that patients seen in outpatient physical therapy practices have extensive health histories, including use of medications for a variety of medical conditions (e.g., hypertension, pulmonary disorders, and depression) and surgical histories (e.g., orthopedic, abdominal, and gynecological surgeries).[13]

The types of data that can be generated from a patient's health history are summarized in Box 1.9.[3,14,15,87] The therapist determines which aspects of the patient's history are more relevant than others and what data need to be obtained from various sources.

BOX 1.8 Key Questions to Consider During the Initial Examination

- What are the most complete and readily available sources for obtaining the patient's history?
- Is there a need to obtain additional information about the patient's presenting health condition or a medical diagnosis if one is available?
- Based on initial working hypotheses, which of the patient's signs and symptoms warrant additional testing by physical therapy or by referral to another health-care practitioner?
- Do the patient's problems seem to fall within or outside the scope of physical therapy practice?
- What types of specific tests and measures should be selected to gather data about the patient's impairments, activity/functional limitations, or extent of participation and resulting disability?
- Based on scientific evidence, which diagnostic tests have a high level of accuracy to identify impairments, functional deficits, or disability?
- What are the most important tests to do first? Which could be postponed until a later visit with the patient?

Sources of information about the patient's history include:

- Self-report health history questionnaires filled out prior to or during the initial visit.
- Interviews with the patient, family, or other significant individuals involved in patient care.
- Review of the medical record.
- Reports from the referral source, consultants, or other health-care team members.

The extent of information about a patient's health history that is necessary or available may be extensive or limited and may or may not be readily accessible prior to the first contact with the patient. Compare, for example, the information available to the therapist working in an acute care facility who has ready access to a patient's medical record versus the home health therapist who may have only a patient's medical diagnosis or brief surgical history. Regardless of the extent of written reports or medical/surgical history available, reviewing this information prior to the initial contact with the patient helps a therapist prioritize the questions asked and areas explored during the interview with the patient.

The interview is crucial for determining a patient's chief concerns and functional status—past, current, and desired. It also helps a therapist see a patient's problems from the patient's own perspective, specifically with regard to the perception of limitations in daily functioning or disability. A patient almost always describes a current problem in terms of limited abilities or perceived quality of life, not the presenting impairment(s). For example, a patient might report, "My elbow really hurts when I pick up something heavy" or "I'm having trouble playing tennis (or bowling or unloading groceries from the car)." During the interview, questions that

BOX 1.9 Information Generated from the Initial History

Demographic Data
- Age, sex, race, ethnicity
- Primary language
- Education

Social History
- Family and caregiver resources
- Cultural background
- Social interactions/support systems

Occupation/Leisure
- Current and previous employment
- Job/school-related activities
- Recreational, community activities/tasks

Growth and Development
- Developmental history
- Hand and foot dominance

Living Environment
- Current living environment
- Expected destination after discharge
- Community accessibility

General Health Status and Lifestyle Habits and Behaviors: Past/Present (Based on Self or Family Report)
- Perception of health/disability
- Lifestyle health risks (smoking, substance abuse)
- Diet, exercise, sleep habits

Medical/Surgical/Psychological History
- Previous inpatient or outpatient services

Medications: Current and Past

Family History
- Health risk factors
- Family illnesses

Cognitive/Social/Emotional Status
- Orientation, memory
- Communication
- Social/emotional interactions

Current Conditions/Chief Complaints or Concerns
- Conditions/reasons physical therapy services sought
- Patient's perceived level of daily functioning and disability
- Patient's needs, goals
- History, onset (date and course), mechanism of injury, pattern and behavior of symptoms
- Family or caregiver needs, goals, perception of patient's problems
- Current or past therapeutic interventions
- Previous outcome of chief complaint(s)

Functional Status and Activity Level
- Current/prior functional status: basic ADL and IADL related to self-care and home
- Current/prior functional status in work, school, community-related IADL

Other Laboratory and Diagnostic Tests

relate to symptoms (in this case, elbow pain) should identify location, intensity, description, and factors that provoke (aggravate) or alleviate symptoms in a 24-hour period.

Collecting health history data through a self-report questionnaire has been shown to be an accurate source of information from patients seen in an outpatient orthopedic physical therapy practice.[17] In addition, depending on a patient's condition and individual situation, the perceptions of family members, significant others, caregivers, or employers are often as important to the overall picture as the patient's own assessment of the current problems.

While taking a health history, it is useful to group the interview questions into categories to keep the information organized. Gathering and evaluating data simultaneously makes it easier to recognize and identify *patterns or clusters of signs and symptoms* and even to begin to formulate one or more initial, "working" hypotheses about the patient's problem(s), which later will be supported or rejected. Making these judgments helps organize and structure the examination.[138,139,167] Experienced therapists tend to form working hypotheses quite early in the examination process, even while reviewing a patient's chart before the initial contact with the patient.[71,72,83,104,176] This enables a therapist to determine and prioritize which definitive tests and measures should be selected for the later portion of the examination.[72]

Systems Review

A brief but relevant screening of the body systems, known as a *systems review*,[3] is performed during the patient interview as a part of the examination process after organizing and prioritizing data obtained from the health history. The greater the number of health-related risk factors identified during the history, the greater is the importance of the review of systems. The systems typically screened by therapists are the cardiovascular and pulmonary, integumentary, musculoskeletal, and neuromuscular systems, although problems in the gastrointestinal and genitourinary systems also may be relevant.[14,16] This screening process gives a general overview of a patient's cognition, communication, and social/emotional responses. Only limited information on the anatomical and physiological status or function of each system is obtained. Table 1.3 identifies each system and gives examples of customary screening procedures used by physical therapists.

NOTE: Some of the information noted in Table 1.3, such as the patient's psychosocial status, may have been gathered previously while reviewing and taking the patient's history and need not be addressed again.

The purpose of screening each system is to identify any abnormalities or deficits that require further or more specific testing by a therapist or another health-care practitioner.[3,14,16,87] The systems review serves to identify a patient's symptoms that may have been overlooked during the investigation of the patient's chief symptoms that precipitated the initial visit to therapy.[16] Findings from the systems review coupled with information about a patient's chief complaints secured from the patient's health history enable a therapist to begin to make

TABLE 1.3 Areas of Screening for the Systems Review

System	Screening
Cardiovascular/pulmonary	Heart rate and rhythm, respiratory rate, and blood pressure; pain or heaviness in the chest or pulsating pain; lightheadedness; peripheral edema
Integumentary	Skin temperature, color, texture, integrity; scars, lumps, growths
Musculoskeletal	Height, weight, symmetry, gross ROM, and strength
Neuromuscular	General aspects of motor control (balance, locomotion, coordination); sensation, changes in hearing or vision; severe headaches
Gastrointestinal and genitourinary	Heartburn, diarrhea, constipation, vomiting, severe abdominal pain, problems swallowing, problems with bladder function, unusual menstrual cycles, pregnancy
Cognitive and social/emotional	Communication abilities (expressive and receptive), cognition, affect, level of arousal, orientation, attentiveness/distractibility, ability to follow directions or learn, behavioral/emotional stressors and responses
General/miscellaneous	Persistent fatigue, malaise, unexplained weight gain or loss, fever, chills, sweats

decisions about the possible causes of a patient's impairments and functional deficits and to distinguish between problems that can and cannot be managed effectively by physical therapy interventions. If a therapist determines that a patient's problems lie outside the scope of physical therapy practice, no additional testing is warranted and referral to another health-care practitioner is appropriate.[3,14,16,51]

Specific Tests and Measures

Once it has been decided that a patient's problems/conditions are most likely amenable to physical therapy intervention, the next determination a therapist must make during the examination process is to decide which aspects of physical function require further investigation through the use of specific tests and measures.

Specific (definitive/diagnostic) tests and measures used by physical therapists provide in-depth information about impairments, activity limitations, participation restrictions/disabilities.[3,45,49,87] The specificity of these tests enables a therapist to support or refute the working hypotheses formulated while taking the patient's health history and performing the systems review. In addition, the data generated from these definitive tests are the means by which the therapist ascertains the possible *underlying causes* of a patient's impairments and functional deficits. These tests also give the therapist a clearer picture of a patient's current condition(s) and may reveal information about the patient not previously identified during the history and systems review. If treatment is initiated, the results of these specific tests and measures establish *objective baselines* from which changes in a patient's physical status as the result of interventions are measured.

Given the array of specific tests available to a therapist for a comprehensive physical therapy examination, the guidelines summarized in Box 1.10 should be considered when determining which definitive tests and measures need to be selected and administered.[3,45,46,133]

BOX 1.10 Guidelines for Selection of Specific Tests and Measures

- Consider why particular tests are performed and how the interpretation of their results may influence the formulation of a diagnosis.
- Select tests and measures that provide accurate information and are valid and reliable and whose efficacy is supported by evidence generated from sound scientific studies.
- Administer tests that target multiple levels of functioning and disability: impairments, activity/functional limitations, the patient's perceived level of participation restrictions.
- Prioritize tests and measures selected to gather in-depth information about key problems identified during the history and systems review.
- Decide whether to administer generic tests or tests that are specific to a particular region of the body.
- Choose tests that provide data specific enough to support or reject working hypotheses formulated during the history and systems review and to determine a diagnosis, prognosis, and plan of care when the data are evaluated.
- Select tests and measures that help determine the types of intervention that most likely are appropriate and effective.
- To complete the examination in a timely manner, avoid collecting more information than is necessary to make informed decisions during the evaluation, diagnosis, and treatment planning phases of management.

There are more than 20 general categories of specific tests and measures commonly performed by physical therapists.[3,164] These tests are selected and administered to target specific impairments of the structure and function of body systems. Typically, testing involves multiple body systems to identify the scope of a patient's impairments. When examining a

patient with chronic knee pain, for example, in addition to performing a thorough musculoskeletal examination, it also would be appropriate to administer tests that identify the impact of the patient's knee pain on the neuromuscular system (by assessing balance and proprioception) and the cardiopulmonary system (by assessing aerobic capacity).

Because many of the health-related conditions as the result of injury or disease discussed in this textbook involve the neuromusculoskeletal system, some examples of specific tests and measures that identify *musculoskeletal and neuromuscular impairments* are noted here. They include but are not limited to:

- Assessment of pain
- Goniometry and flexibility testing
- Joint mobility, stability, and integrity tests (including ligamentous testing)
- Tests of muscle performance (manual muscle testing, dynamometry)
- Posture analysis
- Assessment of balance, proprioception, neuromuscular control
- Gait analysis
- Assessment of assistive, adaptive, or orthotic devices

An in-depth examination of impairments by means of diagnostic tests provides valuable information about the extent and nature of the impairments and is the foundation of the diagnosis(es) made by a physical therapist. A thorough examination of impairments also helps a therapist select the most appropriate types of exercise and other forms of therapeutic intervention for the treatment plan.

Although specific testing of impairments is crucial, these tests do not tell the therapist how the impairments are affecting the patient's functional capabilities. Therefore, every examination should also include use of instruments that specifically measure extent of *activity/functional limitations, participation restrictions, and disability.* These tools, often referred to as *functional outcome measures*, are designed to reflect the impact of a patient's health condition and resulting impairments on functional abilities and health-related quality of life.[6] These instruments typically supply baseline measurements of subjective information against which changes in a patient's function or perceived level of disability are documented over the course of treatment. These tests may be generic, covering a wide range of functional abilities, or specific to a particular body region, such as upper extremity function. Generic instruments can be used to assess the global functioning of patients who have a wide array of health conditions and impairments but yield less site-specific data than regional tests of functional abilities or limitations.[133]

The format of functional testing procedures and instruments varies. Some tests gather information by *self-report* (by the patient or family member);[86] others require *observation and rating of the patient*'s *performance* by a therapist as various functional tasks are carried out.[6] Some instruments measure a patient's ease or difficulty of performing specific physical tasks. Other instruments incorporate temporal (time-based) or spatial (distance-based) criteria, such as measurement of walking speed or distance, in the format.[5] Test scores also can be based on the level of assistance needed (with assistive devices or by another person) to complete a variety of functional tasks.

Indices of disability measure a patient's perception of his or her degree of participation restriction. These self-report instruments usually focus on BADL and IADL, such as the ability or inability to care for one's own needs (physical, social, emotional) or the level of participation in the community that is currently possible, desired, expected, or required. Information gathered with these instruments may indicate that the patient requires consultation and possible intervention by other health-care professionals to deal with some of the social or psychological aspects of disability.

NOTE: It is well beyond the scope or purpose of this text to identify and describe the many tests and instruments that identify and measure physical impairments, functional deficits, or disability. The reader is referred to several resources in the literature that provide this information.[1,5,6,23,98]

Evaluation

Evaluation is a process characterized by the interpretation of collected data. The process involves analysis and integration of information to form opinions by means of a series of sound clinical decisions.[3] Although evaluation is depicted as a distinct entity or phase of the patient management model (see Fig. 1.5), some degree of evaluation goes on at every phase of patient management, from examination through outcome. Interpretation of relevant data, one of the more challenging aspects of patient management, is fundamental to the determination of a diagnosis of dysfunction and prognosis of functional outcomes. By pulling together and sorting out subjective and objective data from the examination, a therapist should be able to determine the following:

- A patient's general health status and its impact on current and potential function
- The acuity or chronicity and severity of the current condition(s)
- The extent of structural and functional impairments of body systems and impact on functional abilities
- Which impairments are related to which activity limitations
- A patient's current, overall level of physical functioning (limitations *and* abilities) compared with the functional abilities needed, expected, or desired by the patient
- The impact of physical dysfunction on social/emotional function
- The impact of the physical environment on a patient's function
- A patient's social support systems and their impact on current, desired, and potential function

The decisions made during the evaluation process may also suggest that additional testing by the therapist or another practitioner is necessary before the therapist can determine a patient's diagnosis and prognosis for positive outcomes from physical therapy interventions. For example, a patient whose

chief complaints are related to episodic shoulder pain but who also indicates during the health history that bouts of depression sometimes make it difficult to work or socialize should be referred for a psychological consultation and possible treatment.[14] Results of the psychological evaluation could be quite relevant to the success of the physical therapy intervention.

Addressing the questions posed in Box 1.11 during the evaluation of data derived from the examination enables a therapist to make pertinent clinical decisions that lead to the determination of a diagnosis and prognosis and the selection of potential intervention strategies for the plan of care.

During the evaluation, it is particularly useful to ascertain if and to what extent relationships exist among measurements of impairments, activity/functional limitations, participation restrictions, and the patient's perceived level of disability. These relationships often are not straightforward as indicated in the following investigations.

FOCUS ON EVIDENCE

In a study of patients with cervical spine disorders,[62] investigators reported a strong correlation between measurements of impairments (pain, ROM, and cervical muscle strength) and functional limitations (functional axial rotation and lifting capacity) but a relatively weak statistical relationship between measurements of functional limitations and the patient's perceived level of disability, as determined by three self-report measures. In another study[169] that compared shoulder ROM with the ability of patients to perform basic self-care activities, a strong correlation was noted between the degree of difficulty of performing these tasks and the extent of shoulder motion limitation.

BOX 1.11 Key Questions to Consider During the Evaluation and Diagnostic Processes

- What is the extent, degree, or severity of structural and functional impairments, activity/functional limitations, or participation restrictions/disability?
- What is the stability or progression of dysfunction?
- To what extent are any identified personal and environmental barriers to functioning modifiable?
- Is the current health condition(s) acute or chronic?
- What actions/events change (relieve or worsen) the patient's signs and symptoms?
- How do preexisting health conditions (comorbidities) affect the current condition?
- How does the information from the patient's medical/surgical history and tests and measures done by other health-care practitioners relate to the findings of the physical therapy examination?
- Have identifiable clusters of findings (i.e., patterns) emerged relevant to the patient's dysfunction?
- Is there an understandable relationship between the patient's extent of impairments and the degree of activity/functional limitation or participation restriction/disability?
- What are the causal factors that seem to be contributing to the patient's impairments, activity/functional limitations, or participation restriction/disability?

Although the results of these studies to some extent are related to the choice of measurement tools, these findings highlight the complexity of evaluating disability and suggest that identifying the strength or weakness of the links among the levels of functioning and disability may help a therapist predict more accurately a patient's prognosis, with the likelihood of functional improvement the result of treatment. Evaluating these relationships and answering the other questions noted in Box 1.11 lays the foundation for ascertaining a diagnosis and prognosis and developing an effective plan of care.

Diagnosis

The term diagnosis can be used in two ways—it refers to either a process or a category (label) within a classification system.[54] Both usages of the word are relevant to physical therapy practice. The diagnosis is an essential element of patient management because it directs the physical therapy prognosis (including the plan of care) and interventions.[3,45,87,144,167,183]

Diagnostic Process

The diagnostic process is a complex *sequence* of actions and decisions that begins with: (1) the collection of data (examination); (2) the analysis and interpretation of all relevant data collected, leading to the generation of working hypotheses (evaluation); and (3) organization of data, recognition of clustering of data (a pattern of findings), formation of a diagnostic hypothesis, and subsequent classification of data into categories (impairment-based diagnoses).[3,36,51,136,145,167,183]

The diagnostic process is also necessary to develop a prognosis (including a plan of care) and is a prerequisite for treatment.[35,77,136,144,167,183] Through the diagnostic process a *physical therapist classifies dysfunction* (most often, movement dysfunction), whereas a physician identifies disease.[51,77,87,136,171] For the physical therapist, the diagnostic process focuses on the *consequences* of a disease or health disorder[183] and is a mechanism by which discrepancies and consistencies between a patient's current level of performance and desired level of function and his or her capacity to achieve that level of function are identified.[3]

Diagnostic Category

A diagnostic classification system developed by physical therapists is useful for delineating the knowledge base and scope of practice of physical therapy.[3,35,54,77,136,144,182] The use of a common diagnostic classification scheme not only guides treatment,[64] it fosters clarity of communication in practice and clinical research.[45,77]

A diagnostic category (clinical classification) is a grouping that identifies and describes patterns or clusters of physical findings (signs and symptoms of impairments of body functions or structures associated with activity/functional limitations, participation restrictions, and the extent of disability). A diagnostic category also describes the impact of a condition on function at the system level (musculoskeletal, neuromuscular, cardiovascular/pulmonary, integumentary) and at the level of the whole person.[3] Within each body system are a number of broad-based diagnostic categories defined by the *primary impairments* and based on clusters of common impairments exhibited by a patient. Box 1.12 lists the impairment-based diagnostic classifications developed by consensus by physical therapists for the musculoskeletal system.[3] The groupings of impairments exhibited by patients with most of the health conditions discussed in this textbook can be classified into at least one of these diagnostic categories.

Patients with different health conditions but similar impairments may be classified by the same diagnostic category. Moreover, it is not uncommon during the diagnostic process for a therapist to identify more than one diagnostic category to describe a patient's impaired function. Complete descriptions of impairment-based diagnostic categories for each body system can be found in the *Guide to Physical Therapist Practice*.[3]

Preferred practice patterns, which are identified by the diagnostic categories, represent consensus-based opinions that outline broad patient management guidelines and strategies used by physical therapists for each diagnostic category.[34,56,183] These patterns are *not* designed to indicate a specific pathway of care, such as an exercise protocol for a specific postoperative condition, but rather are descriptions of all components of patient management from examination through discharge for which physical therapists are responsible. In other words, the preferred practice patterns describe what it is that physical therapists do. For a detailed description of the suggested procedures for each preferred practice pattern for the musculoskeletal, neuromuscular, cardiovascular/pulmonary, and integumentary systems, refer to the *Guide*.[3]

NOTE: The impairment/function-based diagnoses in the clinical practice guidelines developed by the Orthopedic Section of the APTA are an alternative to the diagnostic categories identified in the *Guide* and are based on the classification and coding system described in the ICF. The diagnostic classifications are linked to recommendations for physical therapy interventions based on "best evidence" from the scientific literature.[22,26,27,94,95,107]

BOX 1.12 Diagnostic Classifications for the Musculoskeletal System

- Primary prevention/risk reduction for skeletal demineralization (pattern 4A)
- Impaired posture (pattern 4B)
- Impaired muscle performance (pattern 4C)
- Impaired joint mobility, motor function, muscle performance, and range of motion (ROM) associated with connective tissue dysfunction (pattern 4D)
- Impaired joint mobility, motor function, muscle performance, and ROM associated with localized inflammation (pattern 4E)
- Impaired joint mobility, motor function, muscle performance, ROM, and reflex integrity associated with spinal disorders (pattern 4F)
- Impaired joint mobility, muscle performance, and ROM associated with fracture (pattern 4G)
- Impaired joint mobility, motor function, muscle performance, and ROM associated with joint arthroplasty (pattern 4H)
- Impaired joint mobility, motor function, muscle performance, and ROM associated with bony or soft tissue surgery (pattern 4I)
- Impaired motor function, muscle performance, ROM, gait, locomotion, and balance associated with amputation (pattern 4J)

Prognosis and Plan of Care

After the initial examination has been completed, data have been evaluated, and an impairment-based diagnosis has been established, a prognosis (see Fig. 1.5), including a plan of care, must be determined before initiating any interventions. A *prognosis* is a prediction of a patient's optimal level of function expected as the result of a plan for treatment during an episode of care and the anticipated length of time needed to reach specified functional outcomes.[3,87] Some factors that influence a patient's prognosis and functional outcomes are noted in Box 1.13.

Determining an accurate prognosis is, indeed, challenging even for experienced therapists. The more complex a patient's problems, the more difficult it is to project the patient's optimal level of function, particularly at the onset of treatment. For example, if an otherwise healthy and fit 70-year-old patient who was just discharged from the hospital after a total

BOX 1.13 Factors That Influence a Patient's Prognosis/Expected Outcomes

- Complexity, severity, acuity, or chronicity and expected course of the patient's health condition(s) (pathology), impairments, and activity/functional limitations
- Patient's general health status and presence of comorbidities (e.g., hypertension, diabetes, obesity) and risk factors
- The patient's previous level of functioning or disability
- The patient's living environment
- Patient's and/or family's goals
- Patient's motivation and adherence and responses to previous interventions
- Safety issues and concerns
- Extent of support (physical, emotional, social)

knee arthroplasty is referred for home-based physical therapy services, it is relatively easy to predict the time frame that will be needed to prepare the patient to return to independence in the home and community. In contrast, it may be possible to predict only incremental levels of functional improvement at various stages of rehabilitation for a patient who has sustained multiple fractures and soft tissue injuries as the result of an automobile accident.

In these two examples of establishing prognoses for patients with musculoskeletal conditions, as with most other patient problems, the accuracy of the prognosis is affected in part by the therapist's clinical decision-making ability based on the following[3]:

- Familiarity with the patient's current health condition(s) and the surgical intervention(s) and previous history of diseases or disorders
- Knowledge of the process and time frames of tissue healing
- Experience managing patients with similar surgical procedures, pathological conditions, impairments, and functional deficits
- Knowledge of the efficacy of tests and measures performed, accuracy of the findings, and effectiveness of the physical therapy interventions

Plan of Care

The *plan of care*, an integral component of the prognosis, delineates the following[3]:

- Anticipated goals.
- Expected functional outcomes that are meaningful, utilitarian, sustainable, and measurable.
- Extent of improvement predicted and length of time necessary to reach that level.
- Specific interventions.
- Proposed frequency and duration of interventions.
- Specific discharge plans.

Setting Goals and Outcomes in the Plan of Care

Developing a plan of care involves *collaboration* and *negotiation* between the patient (and, when appropriate, the family) and the therapist.[3,77,87] The *anticipated goals* and *expected outcomes* documented in the plan of care must be patient-centered—that is, the goals and outcomes must be meaningful to the patient. These goals and outcomes also must be measurable and linked to each other. Goals are directed at the reduction or elimination of the physical signs and symptoms of pathology and impairments in body function and/or structure that seem to be limiting the patient's functional abilities.[3] Outcomes are associated with the amelioration of functional deficits and participation restrictions to the greatest extent possible coupled with achieving the optimal level possible of function, general health, and patient satisfaction.[3]

Establishing and prioritizing meaningful, functionally relevant goals and determining expected outcomes requires engaging the patient and/or family in the decision-making process from a therapist's first contact with a patient. Patients come to physical therapy not to get stronger or more flexible, but rather, to be able to perform physical activities they enjoy doing or must do in their lives with ease and comfort. Knowing what a patient wants to be able to accomplish as the result of treatment and ascertaining which accomplishments are the most important to the patient helps a therapist develop and prioritize intervention strategies that target the patient's functional limitations and functionally related impairments. This, in turn, increases the likelihood of successful outcomes from treatment.[120,130] Some key questions a therapist often asks a patient or the patient's extended support system early in the examination while taking the history that are critical for establishing anticipated goals and expected outcomes in the plan of care are listed in Box 1.14.[4,87,120,130]

An integral aspect of effective goal and outcome setting is explaining to a patient how the health condition and identified impairments are associated with the patient's activity/functional limitations and participation restrictions and why specific interventions will be used. Discussing an expected time frame for achieving the negotiated goals and outcomes puts the treatment plan and the patient's perception of progress in a realistic context. This type of information helps a patient and family members set goals that are not just meaningful but realistic and attainable. Setting up *short-term and long-term goals,* particularly for patients with severe or complex problems, is also a way to help a patient recognize incremental improvement and progress during treatment.

The plan of care also indicates the optimal level of improvement that will be reflected by the functional outcomes as well as how those outcomes will be measured. An outline of the specific interventions, their frequency and duration of use, and how the interventions are directly related to attaining the stated goals and outcomes also must appear in

BOX 1.14 Key Questions to Establish and Prioitize Patient-Centered Goals and Outcomes in the Plan of Care

- What activities are most important to you at home, school, work, in the community, or during your leisure time?
- What activities do you currently need help with that you would like to be able to do independently?
- Of the activities you are finding difficult to do or cannot do at all at this time, which ones would you like to be able to do better or do again?
- Of the problems you are having, which ones do you want to try to eliminate or minimize first?
- In what areas do you think you have the biggest problems during the activities you would like to do on your own?
- What are your goals for coming to physical therapy?
- What would you like to be able to accomplish through therapy?
- What would make you feel that you were making progress in achieving your goals?
- How soon do you want to reach your goals?

the plan. Finally, the plan of care concludes with the criteria for discharge. These criteria are addressed following a discussion of elements of intervention in the patient management process.

NOTE: Periodic re-examination of a patient and re-evaluation of a patient's response to treatment may necessitate modification of the initial prognosis and plan of care.

Intervention

Intervention, a component of patient management, refers to any purposeful interaction a therapist has that directly relates to a patient's care[3] (see Fig. 1.5). There are three broad areas of intervention that occur during the course of patient management.[3]

- Coordination, communication, and documentation
- Procedural interventions
- Patient-related instruction

Each of these areas is an essential aspect of the intervention phase of patient management. Absence of just one of these elements can affect outcomes adversely. For example, inclusion of the most appropriate, functionally relevant exercises (procedural intervention) in a treatment program does not lead to a successful outcome if the therapist has not communicated with the necessary parties for an approval or extension of physical therapy services (communication) or if the patient has not learned how to perform the exercises in the program correctly (patient-related instruction). A brief discussion of the three major components of intervention is presented in this section with additional information in the final section of the chapter on exercise instruction, an aspect of patient-related instruction that is most relevant to the focus of this textbook.

Coordination, Communication, and Documentation

The physical therapist is the coordinator of physical therapy care and services and must continually communicate verbally and through written documentation with all individuals involved in the care of a patient. This aspect of intervention encompasses many patient-related administrative tasks and professional responsibilities, such as writing reports (evaluations, plans of care, discharge summaries); designing home exercise programs; keeping records; contacting third-party payers, other health-care practitioners, or community-based resources; and participating in team conferences.

NOTE: Even during the intervention phase of patient management, a therapist might decide that referral to another practitioner is appropriate and complementary to the physical therapy interventions. This requires coordination and communication with other health-care practitioners. For example, a therapist might refer a patient, who is generally deconditioned from a sedentary lifestyle and who is also obese, to a nutritionist for dietary counseling to complement the physical therapy program designed to improve the patient's aerobic capacity (cardiopulmonary endurance) and general level of fitness.

Procedural Interventions

Procedural intervention pertains to the specific procedures used during treatment, such as therapeutic exercise, functional training, or adjunctive modalities (physical agents and electrotherapy). Procedural interventions are identified in the plan of care. Most procedural interventions used by physical therapists, including the many types of therapeutic exercise, are designed to reduce or correct impairments, as depicted in Figure 1.6.

FIGURE 1.6 Manual resistance exercise, a procedural intervention, is a form of therapeutic exercise used during the early stage of rehabilitation if muscle strength or endurance is impaired.

If procedural interventions are to be considered effective, they must result in the reduction or elimination of functional deficits and participation restrictions and, whenever possible, reduce the risk of future dysfunction. Moreover, the efficacy of procedural interventions should be supported by sound evidence, preferably based on prospective, randomized, controlled research studies.

Although the intended outcome of therapeutic exercise programs has always been to enhance a patient's functional capabilities or prevent loss of function, until the past few decades the focus of exercise programs was on the resolution of impairments. Success was measured primarily by the reduction of the identified impairments or improvements in various aspects of physical performance, such as strength, mobility, or balance. It was assumed that if impairments were resolved, improvements in functional abilities would subsequently follow. Physical therapists now recognize that this assumption is not valid. To reduce functional limitations and improve a patient's health-related quality of life, not only should therapeutic exercise interventions be implemented that correct functionally limiting impairments, but whenever possible, exercises should be task-specific—that is, they should be performed using movement patterns that closely match a patient's intended or desired functional activities. In Figure 1.7, strengthening exercises are performed using task-specific lifting patterns.

FIGURE 1.7 Task-specific strengthening exercises are carried out by lifting and lowering a weighted crate in preparation for functional tasks at home or work.

The importance of designing and implementing exercises that closely replicate the desired functional outcomes is supported by the results of many studies, such as the following study.

FOCUS ON EVIDENCE

Task-specific functional training was investigated in a study of the effects of a resistance exercise program on the stair-climbing ability of ambulatory older women.[31] Rather than having the subjects perform resisted hip and knee extension exercises in nonweight-bearing positions, they trained by ascending and descending stairs while wearing a weighted backpack. This activity not only improved muscle performance (strength and endurance), it directly enhanced the subjects' efficiency in stair climbing during daily activities.

Another way to use therapeutic exercise interventions effectively to improve functional ability is to integrate safe but progressively more challenging functional activities that utilize incremental improvements in strength, endurance, and mobility into a patient's daily routine as early as possible in the treatment program. With this functionally oriented approach to exercise, the activities in the treatment program are specific to and directly support the expected functional outcomes. Selection and use of exercise procedures that target more than one goal or outcome are also appropriate and efficient ways to maximize improvements in a patient's function in the shortest time possible.

Effective use of any procedural intervention must include determining the appropriate *intensity, frequency,* and *duration* of each intervention and periodic re-examination of a patient's responses to the interventions. While implementing therapeutic exercise interventions, a patient's response to exercise is continually monitored to decide when and to what extent to increase the difficulty of the exercise program or when to discontinue specific exercises. Each of the chapters of this textbook provides detailed information on factors that influence selection, application, and progression of therapeutic exercise interventions.

Patient-Related Instruction

There is no question that physical therapists perceive themselves as patient educators, facilitators of change, and motivators.[24,47,74,96,116] Patient education spans all three domains of learning: cognitive, affective, and psychomotor domains. Education ideally begins during a patient's initial contact with a therapist and involves the therapist *explaining* information, *asking* pertinent questions, and *listening* to the patient or a family member.

Patient-related instruction, the third aspect of intervention during the patient management process, is the means by which a therapist helps a patient *learn* how to reduce his or her impairments and functional deficits to get better[24] by becoming an active participant in the rehabilitation process. Patient-related instruction first may focus on providing a patient with background information, such as the interrelationships among the primary health condition (pathology) and the resulting impairments and limitations in activity or explaining the purpose of specific interventions in the plan of care. Instruction, such as physical therapist-directed exercise counseling,[165] may be implemented as an alternative to direct supervision of an exercise program and typically focuses on specific aspects of a treatment program, such as teaching a patient, family member, or caregiver a series of exercises to be carried out in a home program; reviewing health and wellness materials; or clarifying directions for safe use of equipment to be used at home.

A therapist must use multiple methods to convey information to a patient or family member, such as one-to-one, therapist-directed instruction, videotaped instruction, or written materials. Each has been shown to have a place in patient education as highlighted by the following studies.

FOCUS ON EVIDENCE

It has been shown that patients, who were taught exercises by a therapist, performed their exercises more accurately in a home program than patients whose sole source of information about their exercises was from reading a brochure.[43] In another study, the effectiveness of three modes of instruction in an exercise program were evaluated. The subjects who received in-person instruction by a therapist or two variations

of videotaped instruction performed their exercise program more accurately than subjects who received only written instructions.[132]

However, written materials, particularly those with illustrations, can be taken home by a patient and used to reinforce verbal instructions from a therapist or videotaped instructions.

To be an effective patient educator, a therapist must possess an understanding of the process of learning, which most often is directed toward learning or modifying motor skills. As a patient educator, a therapist also must be able to recognize a patient's learning style, implement effective teaching strategies, and motivate a patient to *want* to learn new skills, adhere to an exercise program, or change health-related behaviors.

A therapist's skillful, creative use of all three components of intervention, coupled with vigilant re-examination and re-evaluation of the effectiveness of the interventions selected, paves the way for successful outcomes and a patient's discharge from physical therapy services.

Outcomes

Simply stated, outcomes are results. Collection and analysis of outcome data related to health-care services are necessities, not options.[59] Measurement of outcomes is a means by which quality, efficacy, and cost-effectiveness of services can be assessed. Patient-related outcomes are monitored throughout an episode of physical therapy care—that is, intermittently during treatment and at the conclusion of treatment.[120] Evaluation of information generated from periodic re-examination and re-evaluation of a patient's response to treatment enables a therapist to ascertain if the anticipated goals and expected outcomes in the plan of care are being met and if the interventions that have been implemented are producing the intended results. It may well be that the goals and expected outcomes must be adjusted based on the extent of change or lack of change in a patient's function as determined by the level of the interim outcomes. This information also helps the therapist decide if, when, and to what extent to modify the goals, expected outcomes, and interventions in the patient's plan of care.

There are several broad areas of outcomes commonly assessed by physical therapists during the continuum of patient care. They are listed in Box 1.15.

BOX 1.15 Areas of Outcomes Assessed by Physical Therapists

- Level of a patient's physical functioning, including impairments, activity/functional limitations, participation restrictions, and perceived disability
- Extent of prevention or reduced risk of occurrence or recurrence of future dysfunction related to health conditions, associated impairments, activity/functional limitations, participation restrictions, or perceived disability
- Patient's general health status or level of well-being and fitness
- Degree of patient satisfaction

Functional Outcomes

The key to the justification of physical therapy services in today's cost-conscious health-care environment is the identification and documentation of successful patient-centered, functional outcomes that can be attributed to interventions.[3,5,23,55,163] Functional outcomes must be *meaningful, practical,* and *sustainable.*[163] Outcomes that have an impact on a patient's ability to function at work, in the home, or in the community in ways that have been identified as important by the patient, family, significant others, caregivers, or employers are considered *meaningful.* If the formulation of anticipated goals and expected outcome has been a collaborative effort between patient and therapist, the outcomes will be meaningful to the patient. The *practical* aspect of functional outcomes implies that improvements in function have been achieved in an efficient and cost-effective manner. Improvements in function that are maintained over time after discharge from treatment (to the extent possible given the nature of the health condition) are considered *sustainable.*

Measuring Outcomes

The expected outcomes identified in a physical therapy plan of care must be *measurable.* More specifically, changes in a patient's status over time must be *quantifiable.* As noted in the previous discussion of the examination component of the patient management model, many of the specific tests and measures used by physical therapists traditionally have focused on measurement of impairments (i.e., ROM, muscle performance, joint mobility/stability, balance). The reduction of impairments may reflect the impact of interventions on the pathological condition but may or may not translate into improvements in a patient's health-related quality of life, such as safety and functional abilities. Hence, there is the need for measurement not only of impairments but also of a patient's levels of physical functioning and perceived disability to assess accurately patient-related outcomes that include but are not limited to the effectiveness of physical therapy interventions, such as therapeutic exercise.

Impact of interventions on patient-related, functional outcomes. In response to the need to produce evidence that supports the effectiveness of physical therapy interventions for reducing movement dysfunction, a self-report instrument called OPTIMAL (Outpatient Physical Therapy Improvement in Movement Assessment Log) has been developed for measuring the impact of physical therapy interventions on function and has been tested for validity and reliability.[55] The instrument measures a patient's difficulty with or confidence in performing a series of actions, most of which are related to functional mobility, including moving from lying to sitting and sitting to standing, kneeling, walking, running, and climbing stairs, reaching, and lifting. In addition, to assist the therapist with setting goals for the plan of care, the patient is

asked to identify three activities that he or she would like to be able to do without difficulty.

A number of studies that have investigated the benefits of exercise programs for individuals with impaired functional abilities[79,88,141] reflect the trend in research to include an assessment of changes in a patient's health-related quality of life as the result of interventions. Assessment of outcomes related to the reduction of risks of future injury or further impairment, prevention of further functional limitations or disability, adherence to a home program, or the use of knowledge that promotes optimal health and fitness may also help determine the effectiveness of the services provided. To substantiate that the use of physical therapy services for prevention is cost-effective, physical therapists are finding that it is important to collect follow-up data that demonstrate a reduced need for future physical therapy services as the result of interventions directed toward prevention and health promotion activities.

Patient satisfaction. Another area of outcomes assessment that has become increasingly important in physical therapy practice is that of *patient satisfaction*. An assessment of patient satisfaction during or at the conclusion of treatment can be used as an indicator of quality of care. Patient satisfaction surveys often seek to determine the impact of treatment based on the patient's own assessment of his or her status at the conclusion of treatment compared to that at the onset of treatment.[140] Instruments, such as the Physical Therapy Outpatient Satisfaction Survey (PTOPS)[140] or the MedRisk Instrument for Measuring Patient Satisfaction with physical therapy (MRPS),[8,9] also measure a patient's perception of many other areas of care. An important quality of patient satisfaction questionnaires is their ability to discriminate among the factors that influence satisfaction. Identification of factors that adversely influence satisfaction may enable the clinician to take steps to modify these factors to deliver an optimal level of services to patients.[9]

Factors that may influence the extent of patient satisfaction are noted in Box 1.16.[8,9,20,140]

BOX 1.16 Examples of Determinants of Patient Satisfaction*

- Interpersonal attributes of the therapist (communication skills, professionalism, helpfulness, empathy) and the impact on the patient-therapist relationship
- Perception of a therapist's clinical skills
- Extent of functional improvement during the episode of care
- Extent of participation in goal setting in the plan of care
- The acuity of the patient's condition (higher satisfaction in acute conditions)
- Convenience of access to services
- Administrative issues, such as continuity of care, flexible hours for scheduling, waiting time at each visit, duration of treatments, and cost of care

* Determinants are not rank-ordered.

FOCUS ON EVIDENCE

A recent systematic review of the literature addressed the degree of patient satisfaction with musculoskeletal physical therapy care and identified the factors that were associated with high patient satisfaction in outpatient settings across North America and Northern Europe.[66] The review included articles if they were a survey, clinical trial, qualitative study, or patient interview. Only 15 of several thousand articles met the inclusion criteria. A meta-analysis of pooled data from the included studies revealed that on a 1–5 scale (5 being the highest level of satisfaction), the degree of patient satisfaction was 4.41 (95% confidence interval = 4.41–4.46), indicating that patients are highly satisfied with physical therapy care directed toward musculoskeletal conditions. One finding of interest in the studies reviewed is the quality of the patient-therapist relationship consistently ranked higher as an indicator of patient satisfaction than the extent of improvement in the patient's physical functioning as a result of the episode of care.

Discharge Planning

Planning for discharge begins early in the rehabilitation process. As previously noted, criteria for discharge are identified in a patient's plan of care. Ongoing assessment of outcomes is the mechanism by which a therapist determines when discharge from care is warranted. A patient is discharged from physical therapy services when the anticipated goals and expected outcomes have been attained.[3] The discharge plan often includes some type of home program, appropriate follow-up, possible referral to community resources, or re-initiation of physical therapy services (an additional episode of care) if the patient's needs change over time and if additional services are approved.

Discontinuation of services is differentiated from discharge.[3] *Discontinuation* refers to the ending of services prior to the achievement of anticipated goals and expected outcomes. Several factors may necessitate discontinuation of services, which may include a decision by a patient to stop services, a change in a patient's medical status such that progress is no longer possible, or the need for further services cannot be justified to the payer.

In conclusion, the patient management model discussed in this section establishes a comprehensive, systematic approach to the provision of effective and efficient physical therapy care and services to patients and clients. The model is a mechanism to demonstrate the interrelationships among the phases of the continuum of patient care set in a conceptual framework of functioning and disability; it is aimed at improving a patient's function and health-related quality of life. The management model also places an emphasis on reducing risk factors for disease, injury, impairments, or disability

and promoting health and well-being in patients and clients seeking and receiving physical therapy services.

Strategies for Effective Exercise and Task-Specific Instruction

As discussed in the previous section of this chapter, patient-related instruction is an essential element of the intervention phase of patient management. As a patient educator, a therapist spends a substantial amount of time teaching patients, their families, or other caregivers how to perform exercises correctly and safely. Effective strategies founded on principles of motor learning that are designed to help patients initially learn an exercise program under therapist supervision and then carry it out on an independent basis over a necessary period of time contribute to successful outcomes for the patient. Box 1.17 summarizes some practical suggestions for effective exercise instruction.

Preparation for Exercise Instruction

When preparing to teach a patient a series of exercises, a therapist should have a plan that will facilitate learning prior to and during exercise interventions. A positive relationship between therapist and patient is a fundamental aspect for creating a motivating environment that fosters learning. A collaborative relationship should be established when the goals for the plan of care are negotiated. This, of course, occurs before exercise instruction begins. Effective exercise instruction is also based on knowing a patient's learning style—that is, if he or she prefers to learn by watching, reading about, or doing an activity. This may not be known early in treatment, so several methods of instruction may be necessary.

BOX 1.17 Practical Suggestions for Effective Exercise Instruction

- Select a nondistracting environment for exercise instruction.
- Initially teach exercises that replicate movement patterns of *simple* functional tasks.
- Demonstrate proper performance of an exercise (safe vs. unsafe movements; correct vs. incorrect movements). Then have the patient model your movements.
- If appropriate or feasible, initially guide the patient through the desired movement.
- Use clear and concise verbal and written directions.
- Complement written instructions for a home exercise program with illustrations (sketches) of the exercise.
- Have the patient demonstrate an exercise to you as you supervise and provide feedback.
- Provide specific, action-related feedback rather than general, nondescriptive feedback. For example, explain *why* the exercise was performed correctly or incorrectly.
- Teach an entire exercise program in small increments to allow time for a patient to practice and learn components of the program over several visits.

Identifying a patient's attitudes toward exercise helps a therapist determine how receptive a patient is likely to be about learning and adhering to an exercise program. Answers to the following questions may help a therapist formulate a strategy for enhancing a patient's motivation to exercise:

- Does the patient believe exercise will lessen symptoms or improve function?
- Is the patient concerned that exercising will be uncomfortable?
- Is the patient accustomed to engaging in regular exercise?

One method for promoting motivation is to design the exercise program so the least complicated or stressful exercises are taught first, thus ensuring early success. Always ending an exercise session with a successful effort also helps maintain a patient's level of motivation. Additional suggestions to enhance motivation and promote adherence to an exercise program are discussed in this section following an overview of the concepts of motor learning and acquisition of simple to complex motor skills.

Concepts of Motor Learning: A Foundation for Exercise and Task-Specific Instruction

Integration of motor learning principles into exercise instruction optimizes learning an exercise or functional task. An exercise is simply a motor task (a psychomotor skill) that a therapist teaches and a patient is expected to learn.

Motor learning is a complex set of internal processes that involves the acquisition and *relatively permanent* retention of a skilled movement or task through practice.[118,148,149,174,178] In the motor-learning literature a distinction is made between motor performance and motor learning. *Performance* involves acquisition of the ability to carry out a skill, whereas *learning* involves both acquisition and retention.[48,140,148] Therefore, a patient's ability to perform an exercise or any skilled movement early in the motor-learning process is not necessarily representative of having learned the new exercise or skill.

It is thought that motor learning probably modifies the way sensory information in the central nervous system is organized and processed and affects how motor actions are produced. In addition, because motor learning is not directly observable, it must be measured by observation and analysis of how an individual performs a skill.

Types of Motor Tasks

There are three basic types of motor tasks: discrete, serial, and continuous.[148,149]

Discrete task. A discrete task involves an action or movement with a recognizable beginning and end. Isolating and contracting a specific muscle group (as in a quadriceps setting exercise), grasping an object, doing a push-up, locking a wheelchair, and kicking a ball are examples of discrete motor tasks. Almost all exercises, such as lifting and lowering a weight or performing a self-stretching maneuver, can be categorized as discrete motor tasks.

Serial task. A serial task is composed of a series of discrete movements that are combined in a particular sequence. For example, to eat with a fork, a person must be able to grasp the fork, hold it in the correct position, pierce or scoop up the food, and lift the fork to the mouth. Many functional tasks in the work setting, for instance, are serial tasks with simple as well as complex components. Some serial tasks require specific timing between each segment of the task or momentum during the task. Wheelchair transfers are serial tasks. A patient must learn how to position the chair, lock the chair, possibly remove an armrest, scoot forward in the chair, and then transfer from the chair to another surface. Some transfers require momentum, whereas others do not.

Continuous task. A continuous task involves repetitive, uninterrupted movements that have no distinct beginning and ending. Examples include walking, ascending and descending stairs, and cycling.

Recognizing the type of skilled movements a patient must learn to do helps a therapist decide which instructional strategies will be most beneficial for acquiring specific functional skills. Consider what must be learned in the following motor tasks of an exercise program. To self-stretch the hamstrings, a patient must learn how to position and align his or her body and how much stretch force to apply to perform the stretching maneuver correctly. As flexibility improves, the patient must then learn how to safely control active movements in the newly gained portion of the range during functional activities. This requires muscles to contract with correct intensity at an unaccustomed length. In another scenario, to prevent recurrence of a shoulder impingement syndrome or back pain, a patient may need to learn through posture training how to maintain correct alignment of the trunk during a variety of reaching or lifting tasks that place slightly different demands on the body.

In both of these situations, motor learning must occur for the exercise program and functional training to be effective. By viewing exercise interventions from this perspective, it becomes apparent why applications of strategies to promote motor learning are an integral component of effective exercise instruction.

Conditions and Progression of Motor Tasks

If an exercise program is to improve a patient's function, it must include performing and learning a variety of tasks. If a functional training program is to prepare a patient to meet necessary and desired functional goals, it must place demands on a patient under varying conditions. A taxonomy of motor tasks, proposed by Gentile,[48] is a system for analyzing functional activities and a framework for understanding the conditions under which simple to complex motor tasks can be performed. Figure 1.8 depicts these conditions and the dimensions of difficulty of motor tasks.

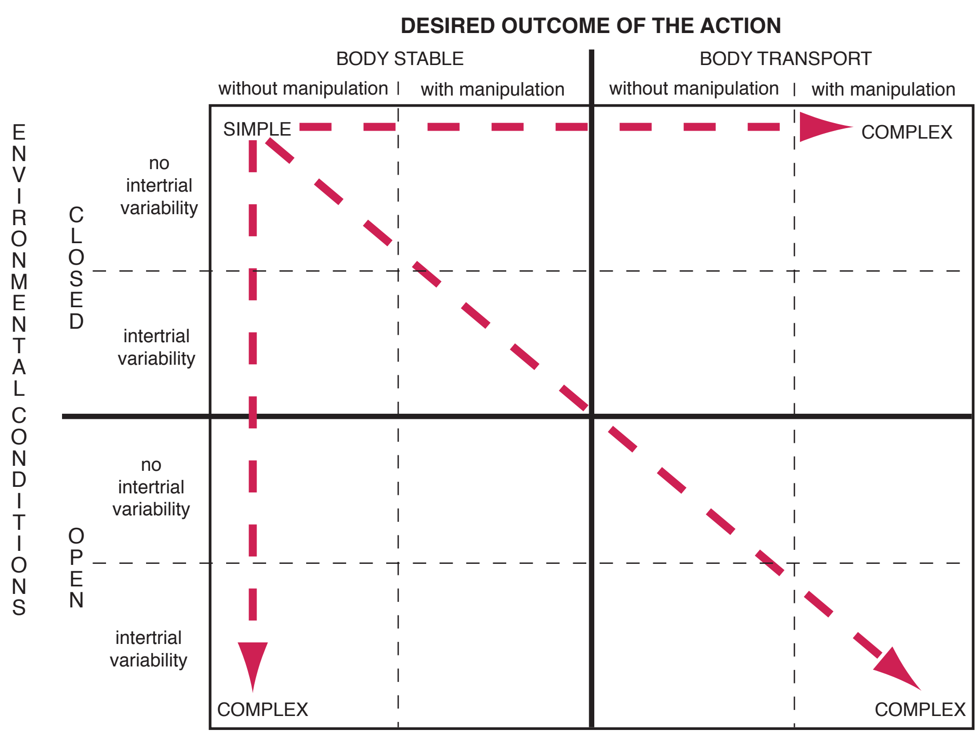

FIGURE 1.8 Taxonomy of motor tasks: dimensions of task difficulty. *(From Dennis, JK, McKeough, DM: Mobility. In May, BJ [ed]: Home Health and Rehabilitation—Concepts of Care. Philadelphia, FA Davis, 1993, p 147, with permission.)*

An understanding of the components of this taxonomy and the interrelationships among its components is a useful framework for a therapist to identify and increase the difficulty of functional activities systematically for a patient with impaired function.

There are four main task dimensions addressed in the taxonomy: (1) the environment in which the task is performed; (2) the inter-trial variability of the environment that is imposed on a task; (3) the need for a person's body to remain stationary or to move during the task; and (4) the presence or absence of manipulation of objects during the task. Examples of simple to complex everyday activities characteristic of each of the 16 different but interrelated task conditions are shown in Figure 1.9.

Closed or open environment. Environmental conditions of a task address whether objects or people (around the patient) are stationary or moving during the task and if the surface on which the task is performed is fixed or moving. A *closed environment* is one in which objects around the patient and the surface on which the task is performed do not move. When a functional task is performed in this type of environment, the patient's complete attention can be focused on performing the task, and the task can be self-paced. Examples of tasks performed in a closed environment are drinking or eating while sitting in a chair and maintaining an erect trunk, standing at a sink and washing your hands or combing your hair, walking in an empty hallway or in a room where furniture placement is consistent.

A more complex environment is an *open environment*. It is one in which objects or other people are in motion or the support surface is unstable during the task. The movement that occurs in the environment is not under the control of the patient. Tasks that occur in open environments include maintaining sitting or standing balance on a movable surface (a balance board or BOSU®) (Fig. 1.10), standing on a moving train or bus, ascending or descending stairs in a crowded stairwell, crossing a street at a busy intersection, or returning a serve in a tennis match or volleyball game. During tasks such as these, the patient must predict the speed and directions of movement of people or objects in the environment or must anticipate the need to make postural or balance adjustments as the support surface moves. Consequently, the patient must pace the performance of the tasks to match the imposed environmental conditions.

Inter-trial variability in the environment: absent or present. When the environment in which a task occurs is constant (unchanging) from one performance of a task to the next, inter-trial variability is absent. The environmental conditions for the task are predictable; therefore, little attention to the task is required, which often enables a patient to perform two tasks at one time. Some examples of tasks without inter-trial variability are practicing safe lifting techniques

		BODY STABLE		BODY TRANSPORT	
		without manipulation	with manipulation	without manipulation	with manipulation
CLOSED	without intertrial variability	Maintaining balance in sitting on bed while caregiver combs hair Maintaining balance in standing in hallway as caregiver buttons coat	Sitting at the table and eating a meal Sitting doing household accounts Sitting at desk to write a letter	Rolling over in bed Sit <=> stand from bed Tub transfers Bed <=> bathroom, using same route daily	Carrying a tray of food or drinks from the kitchen to the living room, using the same tray and same route each time
	with intertrial variability	Maintaining sitting balance on different chairs in the room e.g., rocker, straight-backed chair, sofa. Maintaining standing balance on different surfaces: carpet, wood	Standing in the kitchen unloading a dish-washer Sitting on a low stool in the yard, bending over to weed the vegetable garden	Rolling over in a twin bed and a queen bed Sit <=> stand from different heights and surfaces Up and down curbs of different heights	Carrying a tray of food or drinks from the kitchen to the living room, using different trays and routes each time
OPEN	without intertrial variability	Maintaining balance in a moving elevator	Rearranging packages while standing in a moving elevator	Walking up or down a moving escalator or a moving sidewalk	Rearranging packages while walking up or down the moving escalator
	with intertrial variability	Maintaining sitting or standing balance in a moving bus	Drinking a cocktail on the deck of a cruise ship	Community ambulation Walking through a living room where children are playing	Shopping in the supermarket Walking a precocious pet on a leash

FIGURE 1.9 Activities of daily living in the context of the taxonomy of motor tasks. *(From Dennis, JK, McKeough, DM: Mobility. In May, BJ [ed]: Home Health and Rehabilitation—Concepts of Care, ed. 2. Philadelphia: FA Davis, 1999, p 116, with permission.)*

FIGURE 1.10 Learning to maintain standing balance on an unstable surface is an example of a motor skill that is performed in an open (moving) environment.

using a box of the same dimensions and weight, practicing the tasks of standing up and sitting down from just one height or type of chair, or walking on just one type of surface.

A task becomes more complex when there is inter-trial variability in the environmental conditions—that is, when the demands change from one attempt or repetition of a task to the next. With such variability, the patient must continually monitor the changing demands of the environment and adapt to the new circumstances by using a variety of movement strategies to complete the task. Lifting and carrying objects of different sizes and weight, climbing stairs of different heights, or walking over varying terrain are tasks with inter-trial variability.

Body stable or body transport. In addition to environmental conditions, tasks are analyzed from the perspective of the person doing the task. Tasks that involve maintaining the body in a stable (stationary) position, such as maintaining an upright posture, are considered simple tasks, particularly when performed under closed environmental conditions. When the task requirements involve the patient moving from one place to another (body transport), such as performing a transfer, walking, jumping, or climbing, the task is more complex. When a body transport task is performed in an open environment with inter-trial variability, such as walking in a crowded corridor or on different support surfaces, such as grass, gravel, and pavement, the task becomes even more complex and challenging.

Manipulation of objects—absent or present. Whether performing a task does or does not require upper extremity manipulation activities also affects the degree of difficulty of the task. When a task is performed without manipulating an object, it is considered less complex than if manipulation is a requirement of the task. Carrying a cup of coffee without spilling it while at home alone and walking from one room to another is a more complex task than walking with hands free. Doing the same task in a busy hallway further increases the complexity and difficulty of the task.

In summary, Gentile's taxonomy of motor tasks can be used to analyze the characteristics of functional tasks in the context of the task conditions. The taxonomy provides a framework to structure individual treatment sessions with a patient or to progress the level of difficulty of motor tasks throughout a functional training program.

Stages of Motor Learning

There are three stages of motor learning: cognitive, associative, and autonomous.[37,41,119,148,149] The characteristics of the learner are different at each stage of learning and consequently affect the type of instructional strategies selected by a therapist in an exercise and functional training program.

Cognitive Stage

When learning a skilled movement, a patient first must figure out *what* to do—that is, the patient must learn the goal or purpose and the requirements of the exercise or functional task. Then the patient must learn *how* to do the motor task safely and correctly. At this stage, the patient needs to think about each component or the sequencing of the skilled movement. The patient often focuses on how his or her body is aligned and how far and with what intensity or speed to move. In other words, the patient tries to get the "feel" of the exercise.

Because all of the patient's attention is often directed to the correct performance of the motor task, distractions in the environment, such as a busy, noisy exercise room (an open environment), may initially interfere with learning. During this stage of learning, errors in performance are common, but with practice that includes error correction, the patient gradually learns to differentiate correct from incorrect performance, initially with frequent feedback from a therapist and eventually by monitoring his or her own performance (self-evaluation).

Associative Stage

The patient makes infrequent errors and concentrates on fine-tuning the motor task during the associative stage of learning. Learning focuses on producing the most consistent and efficient movements. The timing of the movements and the distances moved also may be refined. The patient explores slight variations and modifications of movement strategies

while doing the task under different environmental conditions (inter-trial variability). The patient also uses problem-solving to self-correct errors when they do occur. At this stage, the patient requires infrequent feedback from the therapist and, instead, begins to anticipate necessary adjustments and make corrections even before errors occur.

Autonomous Stage

Movements are automatic in this final stage of learning. The patient does not have to pay attention to the movements in the task, thus making it possible to do other tasks simultaneously. Also, the patient easily adapts to variations in task demands and environmental conditions. Little, if any, instruction goes on in this phase of learning unless the patient encounters a recurrence of symptoms or other problems. In fact, most patients are discharged before reaching this stage of learning.

Variables That Influence Motor Learning—Considerations for Exercise Instruction and Functional Training

Motor learning is influenced by many variables, some of which can be manipulated by a therapist during exercise instruction or functional training to facilitate learning. Some of these variables include pre-practice considerations, physical or mental practice, and several forms of feedback. An understanding of these variables and their impact on motor learning is necessary to develop strategies for successful exercise instruction and functional training. A brief overview of these key variables that influence the acquisition and retention of skilled movements during each stage of motor learning is presented in this section. Because concepts and principles of motor learning encompass an extensive body of knowledge, the reader is referred to a number of in-depth resources for additional information.[38,41,48,101,117,118,119,148,149,174]

Pre-Practice Considerations

A number of variables can influence motor learning during an exercise session even before practice begins. A patient's *understanding* of the purpose of an exercise or task, as well as interest in the task, affects skill acquisition and retention. The more meaningful a task is to a patient, the more likely it is that learning will occur. Including tasks the patient identified as important during the initial examination promotes a patient's interest.

Attention to the task at hand also affects learning. The ability to focus on the skill to be learned without distracting influences in the environment promotes learning. Instructions given to a patient prior to practice about where his or her attention should be directed during practice also may affect learning. There is evidence in studies of nonimpaired individuals that learning is enhanced if a person attends to the outcomes of performing a task rather than to the details of the task itself.[106,181] This finding is addressed in more detail in a later discussion of feedback as it relates to motor learning.

Demonstration of a task prior to commencing practice also enhances learning. It is often helpful for a patient to observe another person, usually the therapist or possibly another patient, perform the exercise or functional task correctly and then model those actions. *Pre-practice verbal instructions* that describe the task also may facilitate skill acquisition, but they should be succinct. Extensive information about the task requirements early in the learning process may actually confuse a patient rather than enhance the learning process.

Practice

Motor learning occurs as the direct result of practice—that is, repeatedly performing a movement or series of movements in a task.[90,148,149] Practice is probably the single most important variable in learning a motor skill. The *amount*, *type*, and *variability* of practice directly affect the extent of skill acquisition and retention.[117,148,149] In general, the more a patient practices a motor task, the more readily it is learned. In today's health-care environment, most practice of exercises or functional tasks occurs at home, independent of therapist supervision. A therapist often sets the practice conditions for a home program prior to a patient's discharge by providing guidelines on how to increase the difficulty of newly acquired motor skills during the later stages of learning.

The type of practice strategy selected also has a significant impact on how readily a motor task is learned.[90,101,117,119,148,149,178] Common types of practice are defined in Box 1.18. The type of skill to be learned (discrete, serial, or continuous) and the patient's cognitive status and stage of motor learning determine which practice strategies are more appropriate than others.

Part versus whole practice. *Part practice* has been shown to be most effective in the early stage of learning for acquisition of complex serial skills that have simple and difficult components. Depending on the patient's cognitive status, it is usually necessary to practice only the difficult dimensions of a task before practicing the task as a whole. *Whole practice* is more effective than part practice for acquiring continuous skills, such as walking and climbing stairs, or serial tasks in which momentum or timing of the components is the central focus of the learning process. Whole practice is also used for acquisition of discrete tasks, such as an exercise that involves repetitions of a single movement pattern.

Practice order—blocked, random, and random/blocked. During the initial phase of rehabilitation, practice usually is directed toward learning just a few exercises or functional motor tasks. During the initial (cognitive) stage of learning in which a new motor skill is acquired, *blocked-order practice* is the appropriate choice because it rapidly improves performance of skilled movements. A transition to *random-order* or *random/blocked-order practice* should be made as soon as possible to introduce variability into the learning process. *Variability of practice* refers to making slight adjustments (variations) in the conditions of a task—for example, by varying the support surface or the surroundings where a task is performed.[48,148,149]

Although blocked-order practice initially improves performance at a faster rate than random-order practice, random practice leads to better skill retention and generalizability of

BOX 1.18 Types of Practice for Motor Learning

Part versus Whole Practice

- *Part practice.* A task is broken down into separate dimensions. Individual and usually the more difficult components of the task are practiced. After mastery of the individual segments, they are combined in sequence so the whole task can be practiced.
- *Whole practice.* The entire task is performed from beginning to end and is not practiced in separate segments.

Blocked, Random, and Random/Blocked Practice Orders

- *Blocked-order practice.* The same task or series of exercises or tasks is performed repeatedly under the same conditions and in a predictable order; for example, the patient may consistently practice walking in the same environment, stepping to and from the same height platform, standing up from the same height chair, or lifting containers or equal size or weight; therefore, the task does not change from one repetition to the next.
- *Random-order practice.* Slight variations of the same task are carried out in an unpredictable order; for example, a patient could practice stepping to and from platforms of different heights or practice standing up from chairs of different heights or styles in a random order; therefore, the task changes with each repetition.
- *Random/blocked-order practice.* Variations of the same task are performed in random order, but each variation of the task is performed more than once; for example, the patient rises from a particular height or style chair, and then repeats the same task a second time before moving on to a different height or style chair.

Physical Versus Mental Practice

- *Physical practice.* The movements of an exercise or functional task are actually performed.
- *Mental practice.* A cognitive rehearsal of how a motor task is to be performed occurs prior to actually executing the task; the terms *visualization* and *motor imagery practice* are used synonymously with mental practice.

skills than blocked practice.[117] It is thought that varying tasks just slightly, as is done with random-order practice, requires more cognitive processing and problem-solving than blocked-order practice and, hence, culminates in greater retention of a newly acquired skill after practice has ceased. However, blocked-order practice may be preferable for patients with cognitive deficits, because random-order practice may pose too great a challenge for the patient and subsequently interfere with the learning process.[93]

Random/blocked-order practice results in faster skill acquisition than random-order practice and better retention than blocked-order practice. Because random/blocked-order practice enables a patient to perform a task at least twice before changing to another variation of the task, this form of practice gives a patient the opportunity to identify and then immediately correct errors in a movement sequence before proceeding to the next variation of the task.[48,148]

Physical versus mental practice. Physical practice has long been a hallmark of exercise instruction and functional training in physical therapy, whereas mental practice (motor imagery practice) has its roots in sports psychology and sport-related training.[149,156] About two to three decades ago, the applicability of mental practice as a treatment tool in the rehabilitation of patients with movement impairments began to be investigated for its potential.[177] It is thought that mental rehearsal of a motor task reinforces the cognitive component of motor learning—that is, learning what to do when performing a task and refining how it is executed.

Most studies support the finding that physical practice of motor skills by overtly performing the task is superior to mental practice alone for learning motor tasks.[148,149] However, in sports training and rehabilitation, mental practice, when used in conjunction with physical practice, has been shown to enhance motor skill acquisition at a faster rate than use of physical practice alone.[101,102,117,121]

Feedback

Second only to practicing a motor task, feedback is considered the next most important variable that influences motor learning.[117] *Feedback* is sensory information that is received and processed by the learner during or after performing or attempting to perform a motor skill.[48,117,118,148,149] There are a number of descriptive terms used to differentiate one type of feedback from another. The terms used to describe feedback are based on the source of feedback (*intrinsic* or *augmented/extrinsic*), the focus of feedback (*knowledge of performance* or *knowledge of results*), and the timing or frequency of feedback (the *feedback schedule*). Boxes 1.19 and 1.20 identify and define the various terms associated with the types and scheduling of feedback.

Several factors influence the types of feedback that can occur during exercise instruction or functional training and the effectiveness of feedback for skill acquisition (performance) and skill retention (learning). For example, a patient's physical and cognitive status and the stage of motor learning have a significant impact on the type of feedback that is most effective and the timing and frequency of augmented feedback implemented during practice sessions. It has also been suggested that a therapist should encourage a patient to provide input about his or her receptiveness to the type of feedback or feedback schedule used during practice, particularly once the patient has achieved a beginning level of skill acquisition. This active participation may promote a sense of self-control in the patient and is thought to have a positive impact on learning.[106]

In order to provide the most effective forms of feedback during exercise instruction and functional training, it is useful for a therapist to understand the benefits and limitations of several types and schedules of feedback for skill acquisition and skill retention.

Intrinsic feedback. Intrinsic feedback comes from all of the sensory systems of the learner, not from the therapist, and is

BOX 1.19 Types of Feedback for Motor Learning

Knowledge of Performance (KP) versus Knowledge of Results (KR)

- *KP.* Either intrinsic feedback sensed during a task or immediate, post-task, augmented feedback (usually verbal) about the *nature* or *quality* of the performance of a motor task.
- *KR.* Immediate, post-task, augmented feedback about the *outcome* of a motor task.

Intrinsic Feedback

- Sensory cues that are inherent in the execution of a motor task.
- Arises directly from performing or attempting to perform the task.
- May immediately follow completion of a task or may occur even before a task has been completed.
- Most often involves proprioceptive, kinesthetic, tactile, visual, or auditory cues.

Augmented (Extrinsic) Feedback

- Sensory cues from an external source that are supplemental to intrinsic feedback and that are not inherent in the execution of the task.
- May arise from a mechanical source or from another person.

BOX 1.20 Feedback Schedules

Concurrent versus Postresponse Feedback

- *Concurrent.* Occurs during the performance of a task; also known as "real-time" feedback.
- *Postresponse (terminal).* Occurs after completing or attempting to complete a motor skill.

Immediate, Delayed, and Summary Postresponse Feedback

- *Immediate.* Information that is given directly after a task is completed.
- *Delayed.* Information that is given after a short interval of time has elapsed, allowing time for the learner to reflect on how well or poorly a task was executed.
- *Summary.* Information that is given about the average performance of several repetitions of a motor skill.

Variable versus Constant Feedback

- *Variable (intermittent).* Occurs irregularly, randomly during practice of a motor task.
- *Constant.* Occurs on a regularly recurring, continuous basis during practice of a motor task.

derived from performing or attempting to perform any movement. Intrinsic feedback is inherent in the movement itself—that is, it occurs naturally during or after a task is performed.[48,117,148] It provides ongoing information about the quality of movement during a task and information about the outcomes (results) of a task, specifically if the goal of a task was achieved. In everyday life, intrinsic feedback is a continuous source of information that provides knowledge of performance (KP) and knowledge of results (KR) as a person performs routine activities or tries to learn new motor skills.

Augmented feedback. Information about the performance or results of a task that is *supplemental* to intrinsic feedback is known as augmented feedback.[117,148,149,180] It is also referred to as *extrinsic feedback*.[48,119] Unlike intrinsic feedback, a therapist has control of the type, timing, and frequency of augmented feedback a patient receives during practice. Augmented/extrinsic feedback can be provided during or at the conclusion of a task to give information about the quality of the performance (KP) or the quality of the outcome of a task (KR).

NOTE: Although augmented feedback is a commonly used instructional tool to facilitate motor learning in healthy individuals, it is thought to be particularly necessary when teaching motor skills to patients who may receive inadequate or inaccurate intrinsic feedback as the result of impaired sensory systems from injury or disease.[48,117]

Therapists have many forms of augmented/extrinsic feedback from which to select for exercise instruction and functional training.[48,61,118,180] Some examples include *verbal* or *tactile* feedback directly from a therapist who is interacting with a patient during practice and *visual* or *auditory* feedback from a rehabilitative ultrasound imaging device (Fig. 1.11) or an electromyography (EMG) biofeedback unit. A videotaped replay of a previous performance is another source of augmented visual feedback.

Knowledge of performance versus knowledge of results. Over the past two to three decades, the selection and application of feedback have changed in the clinical setting. Traditionally, a therapist would have a patient focus on sensory information inherent in a motor task (intrinsic feedback) to "get the feel" of movements in the task, such as how it felt to weight shift from side to side while controlling the knees and maintaining standing balance. At the same time the therapist would provide ongoing feedback—usually verbal—about the quality of the patient's posture or knee control (knowledge of performance) during the weight-shifting activity.

However, research, primarily with nonimpaired subjects, has shown that directing a person's attention to the *outcomes* of movements (knowledge of results) rather than to the details of the movements themselves enhances learning (retention of a motor skill) more effectively.[181] Consequently, therapists now tend to place greater emphasis on providing feedback about the outcomes (results) of performing a motor skill.[180]

Going back to the weight-shifting example—to employ knowledge of results during functional training, a therapist should have a patient perform weight shifts by reaching for objects placed in various positions just outside the patient's base of support. By giving the patient a target, the task becomes goal-directed as the patient focuses on the intended results of the movement. The patient, therefore, learns to

judge the effectiveness of his or her movements based on feedback received from external cues.[106,181]

The feedback schedule—timing and frequency of augmented feedback. The scheduling of feedback during practice sessions (see Box 1.18) involves the timing and frequency with which augmented/extrinsic feedback is provided. Feedback schedules affect motor skill acquisition and retention and should be adjusted during the learning process.

Concurrent feedback is a form of augmented feedback that occurs in "real-time" as a patient is performing or attempting to perform a motor task. Visual feedback from a rehabilitative ultrasound-imaging unit (see Fig. 1.11) is an example of concurrent feedback and is useful when a patient is first learning how to perform an isometric contraction of the trunk stabilizing muscles, because no observable movement of the body occurs.

Another form of concurrent feedback, the use of *manual guidance*, which provides tactile cues to the patient, may be necessary for patient safety and may help a patient understand the required movements of an exercise or functional task. However, excessive or long-term use of manual guidance may hamper motor learning, in that it may not allow a patient to make "safe mistakes" while figuring out how to perform a movement. As mentioned in the discussion of the stages of motor learning, self-detection and self-correction of errors are absolutely necessary for learning to occur. The key is to use the least amount of concurrent feedback for the shortest time possible, so the patient does not become reliant on it to carry out a task.[48]

Immediate, postresponse feedback is another form of augmented/extrinsic feedback often used during the initial stage of learning. The therapist provides information, often verbally, about the outcome of the task (KR) immediately after each trial. Although immediate feedback after each trial may enhance early skill acquisition, it too does not allow time for problem-solving by the patient and detection of errors without input from the therapist. Consequently, although initial skill acquisition may occur rather quickly, learning, which includes retention, is delayed.[148]

As alternatives to immediate feedback, *delayed feedback* from the therapist after each repetition of a task or exercise or *summary feedback* after several trials have been completed gives the patient time for self-evaluation and problem-solving as to how the task was performed during practice, which in turn, promotes retention and generalizability of the learned skills. Although use of delayed or summary schedules of feedback is associated with slower skill acquisition than concurrent or immediate feedback after every trial, it is thought that delaying the timing of feedback makes the patient pay attention to intrinsic feedback inherent in the task.[48,148,179]

FIGURE 1.11 (A, B) Use of rehabilitative ultrasound imaging provides augmented (visual) feedback on the screen during exercise instruction to help the patient learn how to activate the transversus abdominis and internal oblique muscles.

FOCUS ON EVIDENCE

The impact of concurrent, immediate postresponse, and summary feedback schedules was investigated in a study of nonimpaired individuals.[179] When subjects practiced a partial weight-bearing activity, those who received concurrent visual feedback (by looking at a scale) achieved the skill more quickly than the subjects who received postresponse feedback (either immediate or summary). However, subjects who received concurrent feedback performed least well on a retention test 2 days after practice ended than the subjects in the two other groups who received postresponse feedback. In addition, summary feedback was found to enhance retention to a greater extent than immediate postresponse feedback.

The frequency with which a therapist provides augmented feedback also should be considered. A basic principle about augmented feedback is that "less is better." Although the greatest frequency of feedback is necessary during the cognitive (initial) stage of learning when a patient is first learning how to perform an exercise or a functional task, excessive or extended use of any form of augmented feedback can create

dependence on the feedback and can be a deterrent to self-detection and correction of errors.[48,148,149] Excessive verbal feedback, for example, provided by a therapist after every trial also can be distracting and may interrupt a patient's attention to the task.

Rather than providing feedback after each repetition of an exercise, a therapist may want to consider varying the frequency of feedback (a variable feedback schedule) by giving the patient input following more than a single repetition and on a variable, less predictable basis. *Variable (intermittent)* feedback during practice has been shown to promote retention of a learned motor skill more effectively than *constant (continuous)* feedback given during or after each repetition.[61] A therapist must keep in mind, however, that constant (continuous) feedback improves skill acquisition (performance) more quickly during the initial stage of learning than variable (intermittent) feedback.[48]

It is also important to fade (decrease) the frequency of feedback over time to avoid the extended use of feedback. S*ummary feedback,* particularly during the associative stage of learning, is an effective strategy to reduce the total amount of feedback given in a practice session. As augmented feedback is faded, a patient must explore slight modifications of a movement strategy and analyze the results. This promotes problem-solving, self-monitoring, and self-correction, all of which enable a patient to perform tasks independently and safely and to transfer learning to new task conditions.

Application of Motor-Learning Principles for Exercise Instruction Summarized

Box 1.21 summarizes the information discussed in this section with regard to qualities of the learner and effective strategies for exercise instruction and functional training founded on the principles and stages of motor learning.

BOX 1.21 Characteristics of the Learner and Instructional Strategies for the Three Stages of Motor Learning[37,118]

COGNITIVE STAGE

Characteristics of the Learner

Must attend only to the task at hand; must think about each step or component; easily distractible; begins to understand the demands of the motor task; starts to get a "feel" for the exercise; makes errors and alters performance, particularly when given augmented feedback; begins to differentiate correct versus incorrect and safe versus unsafe performance.

Instructional Strategies

- Initiate instruction in a nondistracting (closed) environment.
- Identify the purpose and functional relevance of the exercise or functional task.
- Demonstrate the ideal execution of the movements (modeling).
- Initially, guide or assist the patient through the movements. Reduce manual guidance feedback as soon as a patient can safely control movements.
- Point out the distance and speed of the movement (how far or fast to move).
- Emphasize the importance of controlled movements.
- Break complex movements into parts when appropriate.
- Have the patient verbally describe the sequence of component motions.
- Have the patient demonstrate each exercise or task but practice only a few motor tasks. Keep repetitions low and alternate tasks to ensure safety and avoid fatigue.
- Point out sensory cues (intrinsic feedback) to which the patient should attend.
- Provide frequent and explicit positive feedback related to knowledge of performance and knowledge of results.
- Use a variety of forms of feedback (verbal, tactile, visual) and vary.
- Initially use feedback after each repetition to improve performance (acquisition); gradually transition to variable and delayed feedback to enhance learning (retention).
- Introduce the concept of self-evaluation and self-correction of movements.
- Initially, use blocked-order practice; gradually introduce random-order practice
- Allow trial and error to occur within safe limits.

ASSOCIATIVE STAGE

Characteristics of the Learner

Performs movements more consistently with fewer errors or extraneous movements; executes movements in a well-organized manner; refines the movements in the exercise or functional task; detects and self-corrects movement errors when they occur; is less dependent on augmented/extrinsic feedback from the therapist; uses prospective cues and anticipates errors before they occur.

Instructional Strategies

- Emphasize practice of a greater number and variety of movements or tasks.
- Increase the complexity of the exercise or task.
- Vary the sequence of exercise or tasks practiced (random-order practice).

Continued

BOX 1.21 Characteristics of the Learner and Instructional Strategies for the Three Stages of Motor Learning[37,118]—cont'd

- Allow the patient to practice independently, emphasizing problem-solving and use of proprioceptive cues (intrinsic feedback) for error detection.
- Introduce simulation of functional tasks into the practice session.
- Continue to provide augmented feedback regarding knowledge of performance and knowledge of results, but avoid the use of manual guidance.
- Delay feedback or use a variable feedback schedule to give the learner an opportunity to detect movement errors and self-correct them.
- Gradually fade feedback by decreasing the total amount of feedback but increase the specificity of feedback.
- Allow the learner to perform a full set of exercises or several repetitions of a functional task before providing feedback (summary feedback).
- Increase the level of distraction in the exercise environment.
- Prepare the patient to carry out the exercise program in the home or community setting.

AUTONOMOUS STAGE

Characteristics of the Learner

Performs the exercise program or functional tasks consistently and automatically and while doing other tasks; applies the learned movement strategies to increasingly more difficult tasks or new environmental situations; if appropriate, performs the task more quickly or for an extended period of time at a lower energy cost.

Instructional Strategies

- Set up a series of progressively more difficult activities the learner can do independently, such as increasing the speed, distance, and complexity of the exercises or task.
- Suggest ways the learner can vary the original exercise or task and use the task in more challenging situations encountered in everyday activities.
- If the patient is still in therapy, which at most is usually for just a recheck, use little to no feedback unless a significant movement error is noted or a potentially unsafe situation arises.
- Provide assistance, as needed, to integrate the learned motor skills into fitness or sports activities.

Adherence to Exercise

Effective patient-related instruction for a functionally oriented exercise program must include methods to foster *adherence*. This is particularly challenging when a patient is unaccustomed to regular exercise or when an exercise program must be carried out for an extended period of time. Positive outcomes from treatment are contingent not so much on designing the "ideal" exercise program for a patient, but rather, on designing a program that a patient or family will actually follow.[73,74,170]

NOTE: Although the terms *adherence* and *compliance* are often used interchangeably by clinicians and in the literature, the term *adherence* has been selected for this discussion because it has a stronger connotation of active involvement of the patient and patient-therapist collaboration. In contrast, *compliance* tends to imply a more passive connotation with respect to a patient's behavior.

Factors that Influence Adherence to an Exercise Program

Many factors influence adherence to an exercise program.[21,52,57,73,74,100,106,116,153,170] These factors can be grouped into several categories: a patient's characteristics, factors related to a patient's health condition or impairments, and program-related variables.

Patient-Related Factors

The following patient-related factors can have a positive or negative impact on adherence: understanding the health condition, impairments, or exercise program; level of motivation, self-discipline, attentiveness, memory, and willingness and receptivity to change; degree of fatigue or stress; the availability of time to devote to an exercise program; the patient's self-perception of his or her compatibility with the therapist or the degree of control in the exercise program; socioeconomic and cultural background; the beliefs and attitudes about exercise and the value the patient places on the exercise program; and the patient's access to resources. The patient's age and sex also influence adherence to an exercise program, with men having higher adherence rates than women. The association between age and adherence is less clear.

Factors Related to the Health Condition or Impairments

The acuity, chronicity, severity, or stability of the primary health condition and related impairments and presence of comorbidities all have an impact on adherence. Pain is

obviously a deterrent to adherence and, therefore, must be minimized in an exercise program. When impairments are severe or long-standing, setting short-term goals that can be achieved regularly fosters adherence to an exercise program that must be followed over a long period of time.

Program-Related Variables

The complexity and necessary duration of an exercise program; the adequacy of instruction, supervision, and feedback from the therapist; whether the patient has had input into the plan of care; and the continuity of care from an inpatient to a home setting all can have an impact on adherence. Programs that address the interest level and motivational needs of a patient have higher adherence rates. In the outpatient setting, logistics, such as location and scheduling, the program's atmosphere created by the therapist/exercise instructor, as well as the availability of social support and individualized attention or counseling from personnel also are important factors that foster adherence.

Strategies to Foster Adherence

A therapist should expect that most patients will not dutifully adhere to any treatment program, particularly if regular exercise has not been a part of the patient's life prior to the occurrence of disease or injury. The most a therapist can hope to do is implement strategies that foster adherence. Some suggestions from a number of resources in the literature are noted in Box 1.22.[21,52,57,73,74,89,106,116,153,170]

BOX 1.22 Strategies to Foster Adherence to an Exercise Program

- Explore and try to appreciate the patient's beliefs about exercising or the value the patient places on exercising as a means to "get better."
- Help the patient identify personal benefits derived from adhering to the exercise program.
- Explain the rationale and importance of each exercise and functional activity.
- Identify how specific exercises are designed to meet specific patient-centered goals or functional outcomes.
- Allow and encourage the patient to have input into the nature and scope of the exercise program, the selection and scheduling of practice and feedback, and decisions of when and to what extent exercises are progressively made more difficult to enhance a patient's sense of self-control.
- Keep the exercise program as brief as possible.
- Identify practical and functionally oriented ways to do selected exercises during everyday tasks.
- Have the patient keep an exercise log.
- If possible, schedule follow-up visit(s) to review or modify exercises.
- Point out specific exercise-related progress.
- Identify barriers to adherence (not enough time in the day to do the exercises, discomfort during the exercises, lack of necessary equipment); then suggest solutions or modify the exercise program.

Independent Learning Activities

Critical Thinking and Discussion

1. Critically analyze your own, an acquaintance's, or a family member's exercise history. Then identify how a regular regimen of exercise could improve your quality of life or theirs.
2. Research four health conditions (diseases, injuries, or disorders) that result in primary impairments of the (1) musculoskeletal, (2) neuromuscular, (3) cardiovascular/pulmonary, and (4) integumentary systems. Identify characteristic impairments (signs and symptoms) associated with each health condition and hypothesize what activity/functional limitations and participation restrictions are most likely to develop.
3. Why is it essential for a physical therapist to understand and be able to articulate (verbally or in written form) the interrelationships among impairments typically exhibited by patients with various health conditions, activity/functional limitations, participation restrictions, and disability?
4. Last month, you sprained your ankle (inversion sprain). You had to use crutches for several days, but since then you have been walking independently. Pain and swelling still return after vigorous activity, and your ankle feels unstable on uneven terrain. Using a model of functioning and disability as your frame of reference, identify specific activity limitations that would most likely develop in your life as the result of your history and current problems.
5. Using your current knowledge of examination procedures, develop a list of specific tests and measures you would most likely choose to use when examining a patient whose primary impairments affect the (1) musculoskeletal, (2) neuromuscular, (3) cardiovascular and/or pulmonary, and (4) integumentary systems.
6. You have been asked to make recommendations for the adoption of one or more new measurement instruments to be used at your facility for data collection and analysis of patient-centered functional outcomes. Review the literature on musculoskeletal assessment and identify and summarize key features of five instruments that measure activity limitations associated with musculoskeletal impairments of the extremities, neck, or trunk. In addition, identify and summarize key features of five measurement instruments that assess a patient's perceived level of disability.

7. Three individuals just recently sustained a similar fracture of the hip. All underwent an open reduction with internal fixation. The patients are an otherwise healthy 19-year-old college student who was in an automobile accident and wants to return to campus after discharge from the hospital; a 60-year-old person with a somewhat sedentary lifestyle who plans to return home after postoperative rehabilitation and wishes to return to work in an office as soon as possible; and an 85-year-old individual with severe age-related osteoporosis who has been residing in an assisted living facility for the past year. What issues must be considered when identifying anticipated goals and expected outcomes and determining appropriate interventions in the plans of care for these patients? In what ways would goals and expected outcomes differ for these patients?
8. Identify the key components of the patient management model described in this chapter and discuss how each of those components relates to the potential use of therapeutic exercise interventions.
9. Using the taxonomy of motor tasks discussed in this chapter, identify simple to complex activities that are necessary or important in your daily life. Identify at least three activities that fall within each of the 16 condition variables described in the taxonomy.
10. You are seeing a patient in the home setting for follow-up of a postoperative exercise program and progression of functional activities initiated in the hospital. The patient is a 55-year-old computer analyst who had a (L) total knee arthroplasty 10 days ago. You have completed your examination and evaluation. Other than a long-standing history of degenerative arthritis of the (L) knee, the patient has no other significant health-related problems. As you would expect, the patient has pain and limited range of motion of the (L) knee and decreased strength of the (L) lower extremity. The patient is currently ambulating with axillary crutches, weight bearing as tolerated on the (L) lower extremity. (a) Identify the musculoskeletal diagnostic classification (as described in the *Guide to Physical Therapist Practice*[3]) that best describes this patient's impairments. (b) As the patient recovers strength and ROM, design a series of progressively more challenging functional motor tasks the patient could practice with your supervision or independently at home based on the taxonomy of motor tasks described in this chapter.

CHAPTER

2

Prevention, Health, and Wellness

KAREN HOLTGREFE, PT, DHS, OCS

In 1979, following the Surgeon General's report on the health of the nation, the U.S. government developed a national prevention agenda. Today, the Office of Disease Prevention and Health Promotion in the Department of Health and Human Services oversees this agenda through *Healthy People 2020*.[17,24,25] The vision for *Healthy People 2020* is "a society in which all people live long, healthy lives." The four overarching goals of this agenda are: (1) attain high quality, longer lives free of preventable disease, disability, injury, and premature death; (2) achieve health equity, eliminate disparities, and improve health of all groups; (3) create social and physical environments that promote health for all; and (4) promote quality of life, healthy development and healthy behaviors across all life stages.

Key Terms and Concepts

Health. General physical, mental, or spiritual condition of the body.[23,24]

Wellness. A state of good health[23] often achieved through healthy lifestyle choices including the following six dimensions of wellness described by the National Wellness Institute[15]:

- *Social*: Interacting and contributing to one's community or environment.
- *Occupational*: "Personal satisfaction and enrichment in one's life through work."
- *Spiritual*: Finding and living a life that has meaning and purpose.
- *Physical*: Making appropriate nutritional choices and participating in regular physical activity.
- *Intellectual*: Actively using your mind to develop new skills and learn new information.
- *Emotional*: Accepting and managing our feelings in all personal interactions.

Health promotion. Contributing to the growth and development of health[2,23]

Health-Related Quality of Life (HRQOL). The total effect of individual and environmental factors on function and health status, including physical, psychological, and social components.[2] Between 2004 and 2008, 16.3% of persons in the United States rated the HRQOL as poor to fair.[6]

Fitness and Physical Activity. Refer to Chapter 7.

Role of Physical Therapy in *Healthy People 2020*

Two examples of *Healthy People 2020* goals that physical therapists can help address are found in Table 2.1. When assessing the data related to adult physical activity by age group, the percentage of adults participating in moderate physical activity decreases with age. Data from 2008 shows that 38% of adults aged 18 to 24 years meet the objective, whereas only 26% of adults aged 64 to 75 years do.[4] Interestingly, the goal of *Healthy People 2010* was for 50% of all adults over age 18 to participate in at least 30 minutes of moderate intensity physical activity 5 or more days/week. From 2000 to 2008, the average has been 32%. Adults aged 18 to 24 years reached a peak of 42% in 2003 and have since declined to 38%.[4]

Physical therapists have a unique role in providing prevention, health, wellness, and fitness activities needed to address

TABLE 2.1 Examples of Healthy People 2020[25] Goals

Target Area	Objective	2020 Goal (Target) (%)	Baseline (%)	Updated Data 2008 Report (%)
Arthritis, osteoporosis, and chronic back pain	Activity limitations due to chronic back pain*	25	32	31
Physical activity	Adults ≥ 18 years of age who participate in 30 minutes of moderate physical activity for ≥ 5 days/week†	50	32	32

*This objective is to reduce the percentage of individuals with restrictions or functional limitations due to back pain.
†This objective is to increase the percentage (number) of adults who participate in physical activity.

these concerns, and these activities may take many forms. Examples include[2,23]:

- *Screening*: To identify individuals or groups who would benefit from education, intervention, or referral to an appropriate health-care provider.
- *Education*: Provide information on prevention, health, wellness, and fitness topics.
- *Intervention*: Provide interventions as identified from screening sessions.
- *Consultation*: Providing expertise and knowledge.
- *Critical Inquiry*: Obtaining, synthesizing, and utilizing current research, interpreting data, and/or participating in research.
- *Administration*: Planning, developing, and managing all aspects of a prevention or wellness project including budget, human resources, and space.

Examples for various prevention activities can be found in Table 2.2. When developing prevention activities, it is important to note that there are three types of prevention.[2]

- **Primary prevention:** Preventing a target problem or condition in an individual or in a community at risk; for example, developing fitness programs for children to prevent obesity
- **Secondary prevention:** Decreasing the duration and severity of disease; for example, developing resistance programs for individuals with osteoporosis
- **Tertiary prevention:** Decreasing the degree of disability and promoting rehabilitation for individuals with chronic or irreversible diseases; for example, developing fitness programs for individuals with spinal cord injury

The Guide to Physical Therapist Practice[2] (the *Guide*) describes the various ways to contribute to health and wellness

TABLE 2.2 Prevention Activities

Screening Risk Assessment	Health Promotion, Wellness, and Fitness
Scoliosis	Education: Information flyer for parents on identification and treatment for idiopathic scoliosis.
Obesity	Intervention: Develop exercise/fitness program for overweight teens and adults.
Osteoporosis	Education: Develop community education programs related to osteoporosis (importance of exercise, reducing falls in the home). Administration: Develop resistance and weight-bearing exercise class for individuals with osteoporosis.
Falls	Critical Inquiry: Complete a literature review and identify the most appropriate measures of fall risk. Intervention: Develop exercise program to increase strength, balance, and coordination in older adults.
Work site assessment	Consultation: Work with human resource department of a company to identify ways to reduce workplace injuries. Educate: Educate company on proper body mechanics, work station redesign.

including a prevention/risk reduction item at the beginning of each practice pattern. Primary prevention/risk reduction is identified in the *Guide*[2] for:

- Skeletal demineralization.
- Loss of balance and falling.
- Cardiovascular/pulmonary disorders.
- Integumentary disorders.

FOCUS ON EVIDENCE

Norman and her coauthors[16] assessed psychological well-being (Positive Affect Balance Scale), depression symptoms (Edinburgh Postnatal Depressions Scale), and physical activity (minutes per week) in postpartum women. The intervention group (n=62) participated in an exercise and education program for 8 weeks led by a women's health physical therapist, while the control group (n=73) was mailed the same educational material over the 8 weeks. The intervention group had a significant difference in well-being (improvement $p=0.007$) and a reduced risk of developing postpartum depression ($P<0.001$) compared to the control group, but no difference in amount of physical activity.

Identifying Risk Factors

When developing specific programs related to health, wellness, and fitness, it is important to conduct pre-participation screenings and risk assessments. The reader is referred to the American College of Sports Medicine (ACSM)[1] for several tools to assess these factors.

Pre-Participation Screening

Prior to participation in moderate-intensity physical activity, the individual should be asked several questions as summarized in Box 2.1.[22] Individuals who answer yes to one or more questions should consult with their physician before starting the program.

Risk Assessment

The participant should be assessed for risk factors associated with specific conditions such as coronary artery disease (CAD) and osteoporosis, as shown in Box 2.2.[1,14] Identification of risk factors guides the therapist when deciding how to proceed. If multiple risk factors, such as those associated with CAD, are identified, a participant may need to be referred to a physician prior to initiating a program. However, if the risk factors were minimal, the therapist would know to monitor and progress the chosen activities or exercises within established guidelines. (See Chapter 7 for guidelines related to aerobic exercise.)

An individual with identified risk factors for osteoporosis may require additional screening for balance and strength. The therapist can then develop an appropriate resistance program that reduces the risk of injury during these activities. (See Chapter 6 for precautions during resistance training.)

BOX 2.1 Activity Prescreening Questions

1. Have you ever been diagnosed with a heart condition?
2. Have you ever been advised that you should only do physical activity under the direction of a physician?
3. Do you experience chest pain when you do physical activity?
4. Have you experienced chest pain during this past month when not physically active?
5. Have you been diagnosed with arthritis or osteoporosis, or experienced increased pain in your joints when physically active?
6. Are you currently taking prescription drugs for blood pressure or a heart condition?
7. Do you ever lose your balance or lose consciousness?
8. Are you aware of any condition that would prohibit you from doing physical activity?

Determining Readiness to Change

Once the pre-participation screenings and risk assessments are completed and specific programs for an individual are developed, it is important to know whether the person is ready to change. There are multiple theories and models related to health promotion interventions that explain how

BOX 2.2 Risk Factors for Coronary Artery Disease and Osteoporosis

Coronary Artery Disease Risk Factors
- Family history
- Cigarette smoking
- Hypertension
- Hypercholesterolemia
- Impaired fasting glucose level
- Obesity
- Sedentary lifestyle

Osteoporosis Risk Factors
- Bone mineral density score of −2.5 or less
- Postmenopausal
- Caucasian or Asian descent
- Family history
- Low body weight
- Little to no physical activity
- Smoking
- Prolonged bed rest
- Prolonged use of corticosteroids

change occurs. Understanding several of these behavioral change theories can help guide the therapist and client toward the desired outcome.

Behavioral Change Theories

Social cognitive theory. The social cognitive theory (SCT) looks at the belief systems of individuals. An individual must believe that he or she can change a particular behavior and that changing that behavior will lead to the desired outcome.[9,11,13,19,23] For example, a patient may want to lose weight. In addition to the desire to change the behavior causing the increased weight, the patient needs to believe that he or she is capable of succeeding (self-efficacy) and that the outcome will improve his or her health. If the patient decides to use exercise to lose weight, clear instructions on how to perform and progress the exercise program must be given. Feedback on performance must then occur to achieve the final outcome of weight reduction.

Health belief model. The health belief model (HBM) is based on several factors[8,13,18,19,23,26] First, an individual must have sufficient concern about developing an illness (perceived threat). Next, the individual needs to believe that by following the health recommendations it is possible to achieve the desired outcome (perceived benefits) at an acceptable cost (perceived barriers). Using the example of losing weight, an individual would have to believe that being overweight puts him or herself at a greater risk for developing heart disease (perceived threat). This threat may be greater because of a family history. The individual may understand that modifying the diet can help with weight loss but is not sure the best way to proceed. The person may consider joining a weight loss program but may not be sure he or she can afford the weekly fee (perceived barrier). If the perceived threat is sufficiently high, the individual may choose to join the weight loss program to obtain the desired benefit or may choose a different method of weight loss that does not have the same cost.

Transtheoretical model. The transtheoretical model (TTM) looks at the stages required to make changes.[10,11,13,18,23] There are five stages of change:

1. Precontemplation—no intention of making any changes within the next 6 months
2. Contemplation—intends to make changes within the next 6 months
3. Preparation—has begun to take steps toward making the desired change in behavior and plans to make the changes within the next 30 days
4. Action—has changed the behavior for less than 6 months
5. Maintenance—has changed the behavior for more than 6 months

Knowing what stage patients are in and knowing the beliefs they have regarding the need to change, the physical therapist can assist in planning the intervention, particularly if individuals are not ready to make any changes. It allows the therapist to give information needed at the appropriate time.

FOCUS ON EVIDENCE

Using the Health Belief Model (HBM), Chen[7] assessed older adults in a long-term care (LTC) facility about barriers to participating in physical activity. The residents interviewed identified five main barriers: (1) physical frailty and health problems; (2) fear of falling and being injured; (3) past history of little to no physical activity; (4) limited knowledge about physical activity; and (5) restrictions within their environment. The author recommended addressing these modifiable barriers through careful planning, education, and interventions to increase physical activity in older adults living in LTC facilities to prevent further declines in function and mobility.

Additional Factors Affecting the Ability to Change

Motivation. By definition, motivation is how we move ourselves or others to act.[3,5,21,23] When attempting to motivate an individual or group, several dimensions of motivation need to be considered.[3,20] What is the *intrinsic* motivation? Is it the goal or expectation to do one's personal best? Is it the level of difficulty of the task and any potential incentives? Does the individual have the ability to learn and act on what they learn to be successful?

Next, what is the *performance* motivation? Positive and negative reinforcement or rewards can improve performance, as can success or failure. Generally the best performance motivators are low failure and/or high successes.

Finally, what is the *task* motivation? This relates to knowledge and feedback on the performance and should include information on how to improve.

Self-efficacy. Self-efficacy is one's belief or confidence in completing the task, goal, or needed change. Many researchers have identified positive self-efficacy as the key to successful participation in physical activity.[18,21,26]

Developing and Implementing a Program

There are several models associated with program planning in health promotion that are beyond the scope of this chapter. Overall, several steps can be taken to develop and implement prevention, health, and wellness programs.[13] These steps are summarized in Box 2.3. The following case example illustrates the process.

BOX 2.3 Steps to Develop and Implement Prevention, Health, Wellness, and Fitness Programs

Step 1: Identify a Need

- Identify the target audience
  - Children
  - Adults
  - Older adults
  - Industry/business
  - School system
  - Community
  - Specific population (e.g., individuals with Parkinson's disease)

Step 2: Set Goals and Objectives

- Identify the purpose of the program
- Identify the goals to be achieved
  - Screening
  - Education
  - Exercise program
- Identify the objectives of the program

Step 3: Develop the Intervention

- Screenings: Identify valid and reliable right tools to use for the screening
- Education: Develop the program including handouts for participants
- Exercise: Develop the plan for each class
- Logistics
  - Secure a location for the program
  - Consider parking and access to the facility
  - Determine the time and length of the program
  - Determine the number of people who can attend based on the space
  - Identify who will do the program (self or with assistance)
  - Develop the presentation/program; include handouts for the participants
  - Develop a budget; determine costs and charge to the participants

Step 4: Implement the Intervention

- Recognize that even with the best of plans it is important to be adaptable and to be prepared for the unexpected

Step 5: Evaluate the Results

- For an educational session, ask the participants to evaluate the program. Consider an additional follow-up assessment.
- For an exercise class, record baseline data and assess progress during the program and at the end.
- Ask participants to evaluate the exercise program.
- Ask for feedback on what could be done to improve the program (e.g., different time, smaller class, longer sessions).

Case Example: Exercise and Osteoporosis

Step 1: Assessing the Need

- Gretchen, a physical therapist at ABC Hospital, completed an educational session for a local osteoporosis support group on the most recent research related to resistance training and weight-bearing exercise for increasing bone density.
- The women contacted Gretchen and asked her to develop a resistance training exercise class that included free weights and exercise equipment (as found in a fitness club).

NEED: An exercise class that educates women with osteoporosis about the safe way to perform resistance exercise.

Step 2: Set Goals and Objectives

Goal

Develop two education and exercise classes (level 1 and level 2) for women with osteoporosis that emphasize prevention of fractures and proper technique for resistance exercise and weight-bearing activities.

Objectives

1. Educate the participants on the effects of resistance training and weight-bearing exercise on bone health.
2. Educate the participants on the indications and contraindications of certain exercises for individuals with osteoporosis.
3. Educate the participants on the correct techniques for resistance exercise including free weights, resistance band and tubing, and exercise machines.
4. Have participants demonstrate the correct technique when performing resistance exercise.
5. Review implications related to posture and body mechanics during daily activities and during exercise.

Step 3: Develop the Intervention

Gretchen decided to develop two exercise classes: level 1 and level 2. To attend level 2 classes, participants had to complete the level 1 class. The level 1 exercise and education class consisted of four sessions as outlined in Table 2.3.

Gretchen decided to work collaboratively with the Occupational Therapy Department and had them conduct the final class, which emphasized the correct techniques for posture and body mechanics during daily activities. Once the number of classes and general content was decided, Gretchen started planning and developing the program. She:

- Reserved a medium-sized, open room in ABC hospital for 4 weeks and scheduled the class for Tuesday evenings from 6:00 to 8:30
- Determined that the room be set up with tables and chairs in the front for lecture and discussion and with open space in the back for exercising. Classes would be limited to 20 people.

TABLE 2.3 Sample: Level 1 Exercise and Educational Class Content for Osteoporosis

Session	Content/Plan
1	■ Introduction ■ Discussion about yearly height measurement ■ Assessment of balance and flexibility of ankles ■ Review and discussion of good posture ■ Discussion on benefits of resistance training ■ Performed exercises—shoulder blade retraction, chin tucks, sit to stand from a chair, pelvic tilt, heel/toe raises
2	■ Brief review and questions related to material from first class ■ Discussion on prevention of falls ■ Discussion and demonstration of correct technique for performing strengthening exercises ■ Performed exercises with resistance band: arms—bilateral horizontal abduction, rhomboids (band in doorway), leg press ■ Exercise without band—standing hip abduction and step-ups
3	■ Brief review and questions related to previous material ■ Discussion of types of exercise to avoid (increase stress on vertebral bodies) ■ Discussion and demonstration on how to lift weights correctly and how to determine starting weight ■ Discussion on how to increase repetitions and weight during exercise ■ Performed exercises with and without free weights—overhead press, seated fly, standing hip extension, prone bilateral scapular retraction, prone opposite arm and leg lift, lunges
4	■ Review and questions over previous material ■ Occupational therapy reviewed various adaptive equipment ■ Demonstrated correct posture and body mechanics for brushing teeth, making bed, vacuuming ■ Final questions ■ Evaluation of program

- Developed the content and objectives for each exercise/education session including handouts for participants. Put all developed material in a binder by week, including a presenter's checklist of what had to be brought to each class.
- Developed a brochure with times and location of the class and sent it to the osteoporosis support group. The cost of the level 1 exercise and education program was $25. Interested participants were to call and reserve a spot in the class.

Step 4: Implement the Program

The program had 10 participants and took place as scheduled for 4 weeks.

Step 5: Evaluate the Program

Participants were given a course evaluation sheet to complete regarding the location, time, content, and overall satisfaction with the program. In addition, Gretchen evaluated the participants' interest in the proposed level 2 class that would take place in a fitness center with equipment and consist of three sessions.

The overall evaluation of the program was positive, with a few individuals preferring a different day of the week or time of day for attendance. Altogether, 8 of the 10 participants were interested in participating in the level 2 class.

Additional Considerations for Developing Prevention, Health, and Wellness Programs

The following are additional points to consider[12]:

- The exercise or activity has to be specific to the goals of the individual. An individual training to run a marathon needs to run, not ride a bike. Specific principles and procedures for resistance training and aerobic exercise training can be found in Chapters 6 and 7, respectively.
- Consider asking the participants during the "assessing the need" component about what would motivate individuals to participate, and then incorporate some of their suggestions.
- For children, the program should be fun and less structured but should take place for a specified period of time. The recommended amount of physical activity for children is 60 minutes (moderate and vigorous) every day.[5]
- For older adults, the program should start slowly to allow the participants to experience success. Consideration

should be given to how the individuals can incorporate the various exercises or activities into their daily routines. The facility where the program is conducted should be well lit and easily accessible.

- If screenings are conducted, handouts with the results and with follow-up recommendations should be given to the participants.
- When making handouts for participants, keep in mind the audience. For children, make them colorful and fun. For older adults, make the print larger. Keep the language simple. Limit the amount of medical terminology used. Write information as clearly as possible.
- Include pictures of exercises whenever possible.
- Consider the time commitment for you and the participants and the cost involved.

Table 2.4 lists issues related to exercise adherence.

TABLE 2.4 Issues Affecting Exercise Adherence

Poor	Good
Poor or limited leadership	Effective leadership
Inconvenient time of class or program	Part of regular routine
Injury	No injury
Boredom with exercise	Enjoyment—fun—variety
Poor individual commitment	Social support from group
Unaware of any progress being made	Regular updates on progress
Poor family support—disapproval	Family approval; positive reinforcement

Independent Learning Activities

Critical Thinking and Discussion

1. In the case example for developing an exercise program for women with osteoporosis, a second class (level 2) was proposed. Develop the level 2 class. Follow the steps outlined for developing and implementing this program including the content of each exercise session, use of fitness equipment for individuals with osteoporosis, and any handouts needed.
2. In this chapter, the differences in primary, secondary, and tertiary prevention were reviewed. For each of these categories, describe one screening program and one wellness program (exercise or education) that a physical therapist could provide.
3. In Table 2.1, one of the *Healthy People 2020* goals is to reduce the activity limitations (functional limitations) of individuals with chronic low back pain. Describe the limitations to achieving this goal using one of the behavioral change theories. Identify strategies for obtaining this goal.
4. Using the five steps identified in this chapter, develop a prevention and wellness program for a group of fifth and sixth grade boys and girls (10 to 12 years of age) who have been identified as being at risk for type II diabetes because of obesity and sedentary lifestyle. Refer to Chapter 6 for special considerations when developing exercise programs for children.

CHAPTER 3

Range of Motion

Range of motion is a basic technique used for the examination of movement and for initiating movement into a program of therapeutic intervention. Movement that is necessary to accomplish functional activities can be viewed, in its simplest form, as muscles or external forces moving bones in various patterns or ranges of motions. When a person moves, the intricate control of the muscle activity that causes or controls the motion comes from the central nervous system. Bones move with respect to each other at the connecting joints. The structure of the joints, as well as the integrity and flexibility of the soft tissues that pass over the joints, affects the amount of motion that can occur between any two bones. The full motion possible is called the ***range of motion*** (ROM). When moving a segment through its ROM, all structures in the region are affected: muscles, joint surfaces, capsules, ligaments, fasciae, vessels, and nerves. ROM activities are most easily described in terms of joint range and muscle range. To describe joint range, terms such as flexion, extension, abduction, adduction, and rotation are used. Ranges of available joint motion are usually measured with a goniometer and recorded in degrees.[16] Muscle range is related to the functional excursion of muscles.

Functional excursion is the distance a muscle is capable of shortening after it has been elongated to its maximum.[26] In some cases the functional excursion, or range of a muscle, is directly influenced by the joint it crosses. For example, the range for the brachialis muscle is limited by the range available at the elbow joint. This is true of one-joint muscles (muscles with their proximal and distal attachments on the bones on either side of one joint). For two-joint or multijoint muscles (those muscles that cross over two or more joints), their range goes beyond the limits of any one joint they cross. An example of a two-joint muscle functioning at the elbow is the biceps brachii muscle. If it contracts and moves the elbow into flexion and the forearm into supination while simultaneously moving the shoulder into flexion, it shortens to a point known as *active insufficiency*, where it can shorten no more. This is one end of its range. The muscle is lengthened full range by extending the elbow, pronating the forearm, and simultaneously extending the shoulder. When fully elongated, it is in a position known as *passive insufficiency*. Two-joint or multijoint muscles normally function in the midportion of their functional excursion, where ideal length-tension relations exist.[26]

To maintain normal ROM, the segments must be moved through their available ranges periodically, whether it is the available joint range or muscle range. It is recognized that many factors, such as systemic, joint, neurological, or muscular diseases; surgical or traumatic insults; or simply inactivity or immobilization for any reason, can lead to decreased ROM. Therapeutically, ROM activities are administered to maintain joint and soft tissue mobility to minimize

loss of tissue flexibility and contracture formation.[7] Extensive research by Robert Salter has provided evidence of the benefits of movement on the healing of tissues in various pathological conditions in both the laboratory and clinical settings.[20-25]

The principles of ROM described in this chapter do not encompass stretching to increase range. Principles and techniques of stretching and joint manipulation for treating impaired mobility are described in Chapters 4 and 5.

Types of ROM Exercises

- **Passive ROM.** Passive ROM (PROM) is movement of a segment within the unrestricted ROM that is produced entirely by an *external force*; there is little to no voluntary muscle contraction. The external force may be from gravity, a machine, another individual, or another part of the individual's own body.[9] PROM and passive stretching are not synonymous. (See Chapter 4 for definitions and descriptions of passive stretching.)
- **Active ROM.** Active ROM (AROM) is movement of a segment within the unrestricted ROM that is produced by active contraction of the *muscles* crossing that joint.
- **Active-Assistive ROM.** Active-assistive ROM (A-AROM) is a type of AROM in which assistance is provided manually or mechanically by an outside force because the prime mover muscles need assistance to complete the motion.

Indications, Goals, and Limitations of ROM VIDEO 3.1

Passive ROM

Indications for PROM

- In the region where there is acute, inflamed tissue, passive motion is beneficial; active motion would be detrimental to the healing process. Inflammation after injury or surgery usually lasts 2 to 6 days.
- When a patient is not able to or not supposed to actively move a segment(s) of the body, as when comatose, paralyzed, or on complete bed rest, movement is provided by an external source.

Goals for PROM

The primary goal for PROM is to decrease the complications that would occur with immobilization, such as cartilage degeneration, adhesion and contracture formation, and sluggish circulation.[9,20,25] Specifically, the goals are to:

- Maintain joint and connective tissue mobility.
- Minimize the effects of the formation of contractures.
- Maintain mechanical elasticity of muscle.
- Assist circulation and vascular dynamics.
- Enhance synovial movement for cartilage nutrition and diffusion of materials in the joint.
- Decrease or inhibit pain.
- Assist with the healing process after injury or surgery.
- Help maintain the patient's awareness of movement.

Other Uses for PROM

- When a therapist is examining inert structures, PROM is used to determine limitations of motion, joint stability, muscle flexibility and other soft tissue elasticity.
- When a therapist is teaching an active exercise program, PROM is used to demonstrate the desired motion.
- When a therapist is preparing a patient for stretching, PROM is often used preceding the passive stretching techniques.

Limitations of Passive Motion

True passive, relaxed ROM may be difficult to obtain when muscle is innervated and the patient is conscious. Passive motion *does not*:

- Prevent muscle atrophy.
- Increase strength or endurance.
- Assist circulation to the extent that active, voluntary muscle contraction does.

Active and Active-Assistive ROM

Indications for AROM

- When a patient is able to contract the muscles actively and move a segment with or without assistance, AROM is used.
- When a patient has weak musculature and is unable to move a joint through the desired range (usually against gravity), A-AROM is used to provide enough assistance to the muscles in a carefully controlled manner so the muscle can function at its maximum level and be progressively strengthened. Once patients gain control of their ROM, they are progressed to manual or mechanical resistance exercises to improve muscle performance for a return to functional activities (see Chapter 6).
- When a segment of the body is immobilized for a period of time, AROM is used on the regions above and below the immobilized segment to maintain the areas in as normal a condition as possible and to prepare for new activities, such as walking with crutches.
- AROM can be used for aerobic conditioning programs (see Chapter 7) and is used to relieve stress from sustained postures (see Chapter 14).

Goals for AROM

If there is no inflammation or contraindication to active motion, the same goals of PROM can be met with AROM. In addition, there are physiological benefits that result from active muscle contraction and motor learning from voluntary muscle control. Specific goals are to:

- Maintain physiological elasticity and contractility of the participating muscles.

- Provide sensory feedback from the contracting muscles.
- Provide a stimulus for bone and joint tissue integrity.
- Increase circulation and prevent thrombus formation.
- Develop coordination and motor skills for functional activities.

Limitations of Active ROM

For strong muscles, active ROM *does not* maintain or increase strength. It also *does not* develop skill or coordination except in the movement patterns used.

Precautions and Contraindications to ROM Exercises

Although both PROM and AROM are contraindicated under any circumstance when motion to a part is disruptive to the healing process (Box 3.1), complete immobility leads to adhesion and contracture formation, sluggish circulation, and a prolonged recovery time. In light of research by Salter[22] and others,[14] early, continuous PROM within a pain-free range has been shown to be beneficial to the healing and early recovery of many soft tissue and joint lesions (discussed later in the chapter). Historically, ROM has been contraindicated immediately after acute tears, fractures, and surgery; but because the benefits of controlled motion have demonstrated decreased pain and an increased rate of recovery, early controlled motion is used so long as the patient's tolerance is monitored.

It is imperative that the therapist recognizes the value as well as potential abuse of motion and stays within the range, speed, and tolerance of the patient during the acute recovery stage.[9] Additional trauma to the part is contraindicated. Signs of too much or the wrong motion include increased pain and increased inflammation (greater swelling, heat, and redness). See Chapter 10 for principles of when to use the various types of passive and active motion therapeutically.

Usually, AROM of the upper extremities and limited walking near the bed are tolerated as early exercises after myocardial infarction, coronary artery bypass surgery, and percutaneous transluminal coronary angioplasty.[2,8] Careful monitoring of symptoms, perceived exertion, and blood pressure is necessary. If the patient's response or the condition is life-threatening, PROM may be carefully initiated to the major joints along with some AROM to the ankles and feet to avoid venous stasis and thrombus formation. Individualized activities are initiated and progress gradually according to the patient's tolerance.[2,8]

BOX 3.1 Summary of Precautions and Contraindications to Range of Motion Exercises

ROM should not be done when motion is disruptive to the healing process.

- Carefully controlled motion within the limits of pain-free motion during early phases of healing has been shown to benefit healing and early recovery.
- Signs of too much or the wrong motion include increased pain and inflammation.

ROM should not be done when patient response or the condition is life-threatening.

- PROM may be carefully initiated to major joints and AROM to ankles and feet to minimize venous stasis and thrombus formation.
- After myocardial infarction, coronary artery bypass surgery, or percutaneous transluminal coronary angioplasty, AROM of upper extremities and limited walking are usually tolerated under careful monitoring of symptoms.

Note: ROM is not synonymous with stretching. For precautions and contraindications to passive and active stretching techniques, see Chapters 4 and 5.

Principles and Procedures for Applying ROM Techniques

Examination, Evaluation, and Treatment Planning

1. Examine and evaluate the patient's impairments and level of function, determine any precautions and their prognosis, and plan the intervention.
2. Determine the ability of the patient to participate in the ROM activity and whether PROM, A-ROM, or AROM can meet the immediate goals.
3. Determine the amount of motion that can be applied safely for the condition of the tissues and health of the individual.
4. Decide what patterns can best meet the goals. ROM techniques may be performed in the:
   a. *Anatomic planes of motion:* frontal, sagittal, transverse
   b. *Muscle range of elongation:* antagonistic to the line of pull of the muscle
   c. *Combined patterns:* diagonal motions or movements that incorporate several planes of motion
   d. *Functional patterns:* motions used in activities of daily living (ADL)
5. Monitor the patient's general condition and responses during and after the examination and intervention; note any change in vital signs, in the warmth and color of the segment, and in the ROM, pain, or quality of movement.
6. Document and communicate findings and intervention.
7. Re-evaluate and modify the intervention as necessary.

Patient Preparation

1. Communicate with the patient. Describe the plan and method of intervention to meet the goals.
2. Free the region from restrictive clothing, linen, splints, and dressings. Drape the patient as necessary.
3. Position the patient in a comfortable position with proper body alignment and stabilization but that also allows you to move the segment through the available ROM.
4. Position yourself so proper body mechanics can be used.

Application of Techniques

1. To control movement, grasp the extremity around the joints. If the joints are painful, modify the grip, still providing support necessary for control.
2. Support areas of poor structural integrity, such as a hypermobile joint, recent fracture site, or paralyzed limb segment.
3. Move the segment through its complete pain-free range to the point of tissue resistance. Do not force beyond the available range. If you force motion, it becomes a stretching technique.
4. Perform the motions smoothly and rhythmically, with 5 to 10 repetitions. The number of repetitions depends on the objectives of the program and the patient's condition and response to the treatment.

Application of PROM

1. During PROM the force for movement is external; it is provided by a therapist or mechanical device. When appropriate, a patient may provide the force and be taught to move the part with a normal extremity.
2. No active resistance or assistance is given by the patient's muscles that cross the joint. If the muscles contract, it becomes an active exercise.
3. The motion is carried out within the free ROM—that is, the range that is available without forced motion or pain.

Application of AROM

1. Demonstrate the motion desired using PROM; then ask the patient to perform the motion. Have your hands in position to assist or guide the patient if needed.
2. Provide assistance only as needed for smooth motion. When there is weakness, assistance may be required only at the beginning or the end of the ROM, or when the effect of gravity has the greatest moment arm (torque).
3. The motion is performed within the available ROM.

ROM Techniques

The descriptions of positions and ROM techniques in this section may be used for PROM as well as A-AROM and AROM. When making the transition from PROM to AROM, gravity has a significant impact especially in individuals with weak musculature. When the segment moves up against gravity, it may be necessary to provide assistance to the patient. However, when moving parallel to the ground (gravity eliminated or gravity neutral), the part may need only to be supported while the muscles take the part through the range. When the part moves downward, with gravity causing the motion, muscles antagonist to the motion become active and may need assistance in controlling the descent of the part. The therapist must be aware of these effects and modify the patient's position if needed to meet desired goals for A-AROM and AROM. Principles and techniques for progression to manual and mechanical resistance ROM to develop strength are described in Chapter 6.

CLINICAL TIP

- When transitioning from PROM to AROM, vary patient position in order to use gravity to either assist or resist the motion.
- Functional activities that are antigravity will require assistance when muscles are less than 3/5 in strength.

The following descriptions are, for the most part, with the patient in the supine position. Alternate positions for many motions are possible and, for some motions, necessary. For efficiency, perform all motions possible in one position; then change the patient's position and perform all appropriate motions in that position, progressing the treatment with minimal turning of the patient. Individual body types or environmental limitations might necessitate variations of the suggested hand placements. Use of good body mechanics by the therapist while applying proper stabilization and motion to the patient to accomplish the goals and avoid injury to weakened structures is the primary consideration.

NOTE: The term *upper or top hand* means the hand of the therapist that is toward the patient's head; *bottom or lower hand* refers to the hand toward the patient's foot. Antagonistic ROMs are grouped together for ease of application.

Upper Extremity

Shoulder: Flexion and Extension (Fig. 3.1)

VIDEO 3.2

Hand Placement and Procedure

- Grasp the patient's arm under the elbow with your lower hand.
- With the top hand, cross over and grasp the wrist and palm of the patient's hand.
- Lift the arm through the available range and return.

NOTE: For normal motion, the scapula should be free to rotate upward as the shoulder flexes. If motion of only the glenohumeral joint is desired, the scapula is stabilized as described in the chapter on stretching (see Chapter 4).

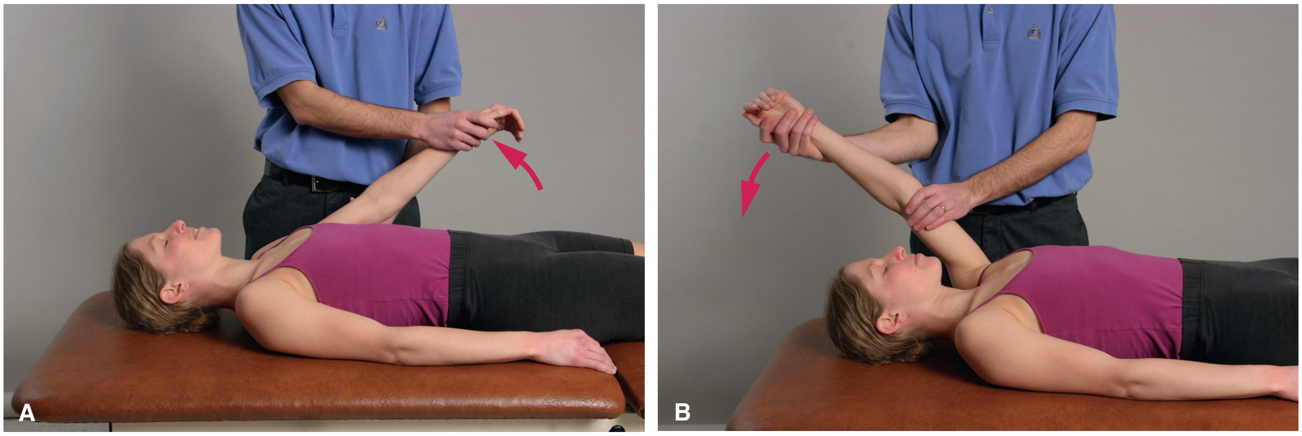

FIGURE 3.1 Hand placement and positions for (A) initiating and (B) completing shoulder flexion.

Shoulder: Extension (Hyperextension) (Fig. 3.2)

To obtain extension past zero, position the patient's shoulder at the edge of the bed when supine or position the patient side-lying, prone, or sitting.

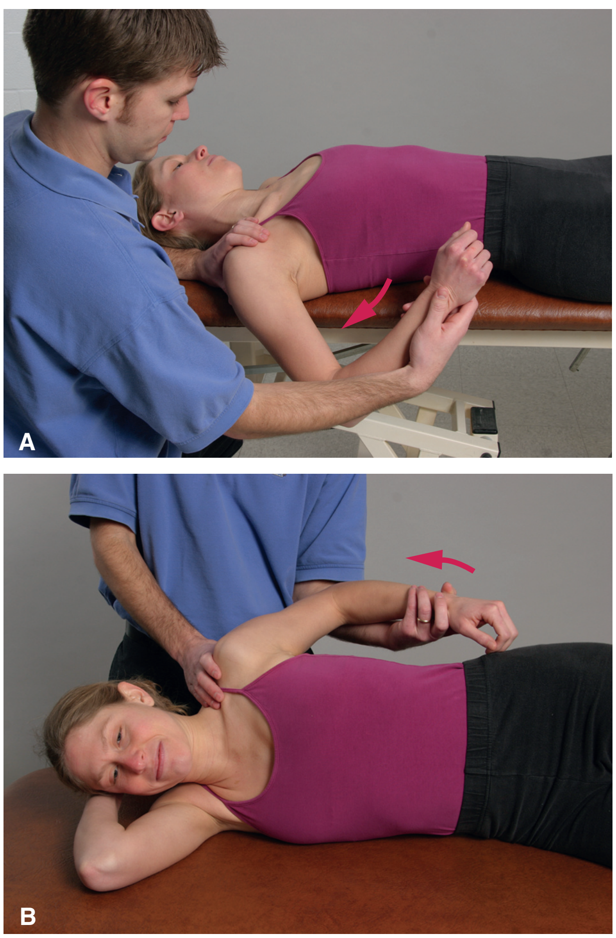

FIGURE 3.2 Hyperextension of the shoulder (A) with the patient at the edge of the bed and (B) with the patient side-lying.

Shoulder: Abduction and Adduction (Fig. 3.3)

Hand Placement and Procedure

Use the same hand placement as with flexion, but move the arm out to the side. The elbow may be flexed.

NOTE: To reach full range of abduction, there must be external rotation of the humerus and upward rotation of the scapula.

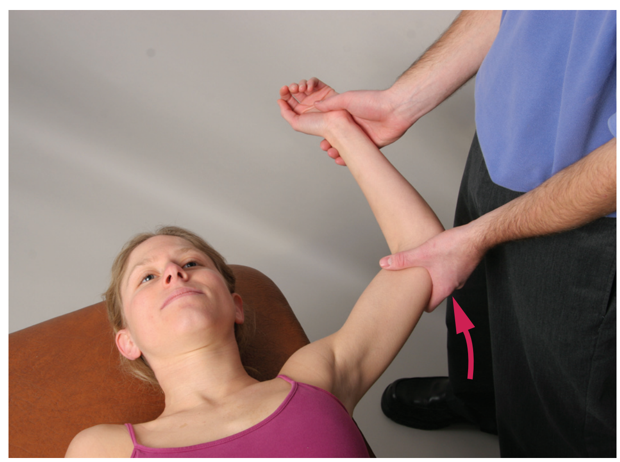

FIGURE 3.3 Abduction of the shoulder with the elbow flexed.

Shoulder: Internal (Medial) and External (Lateral) Rotation (Fig. 3.4)

If possible, the arm is abducted to 90°; the elbow is flexed to 90°; and the forearm is held in neutral position. Rotation may also be performed with the patient's arm at the side of the thorax, but full internal rotation is not possible in this position.

Hand Placement and Procedure

- Grasp the hand and the wrist with your index finger between the patient's thumb and index finger.
- Place your thumb and the rest of your fingers on either side of the patient's wrist, thereby stabilizing the wrist.

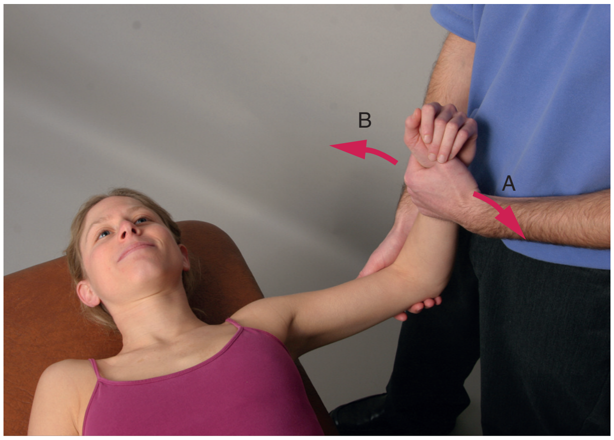

FIGURE 3.4 The 90/90 position for initiating **(A)** internal and **(B)** external rotation of the shoulder.

- With the other hand, stabilize the elbow.
- Rotate the humerus by moving the forearm like a spoke on a wheel.

Shoulder: Horizontal Abduction (Extension) and Adduction (Flexion) (Fig. 3.5)

To reach full horizontal abduction, position the patient's shoulder at the edge of the table. Begin with the arm either flexed or abducted 90°.

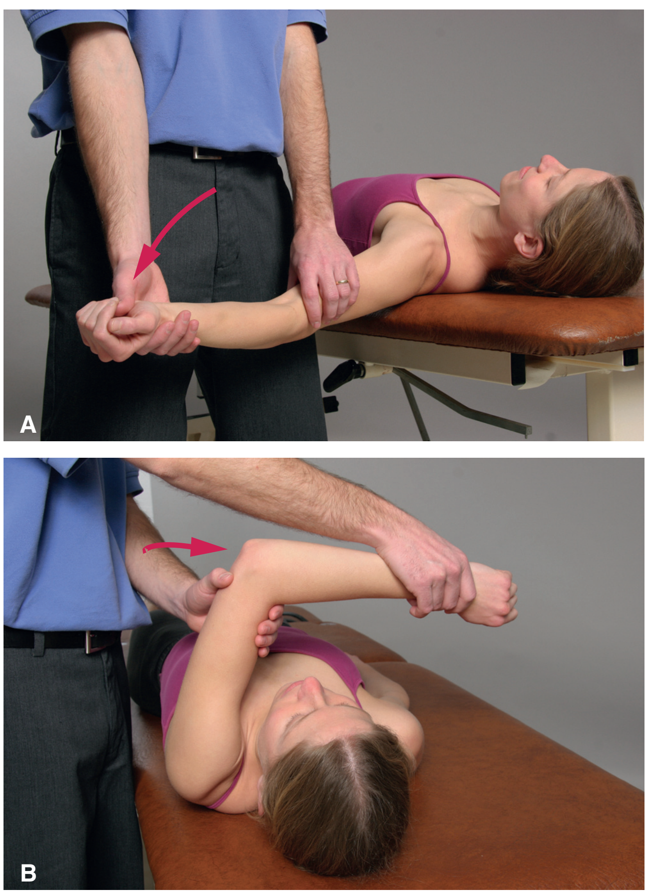

FIGURE 3.5 Horizontal **(A)** abduction and **(B)** adduction of the shoulder.

Hand Placement and Procedure

Hand placement is the same as with flexion, but turn your body and face the patient's head as you move the patient's arm out to the side and then across the body.

Scapula: Elevation/Depression, Protraction/Retraction, and Upward/Downward Rotation (Fig. 3.6)

Position the patient prone, with his or her arm at the side (Fig. 3.6A), or side-lying, facing toward you. Drape the patient's arm over your bottom arm (Fig. 3.6B).

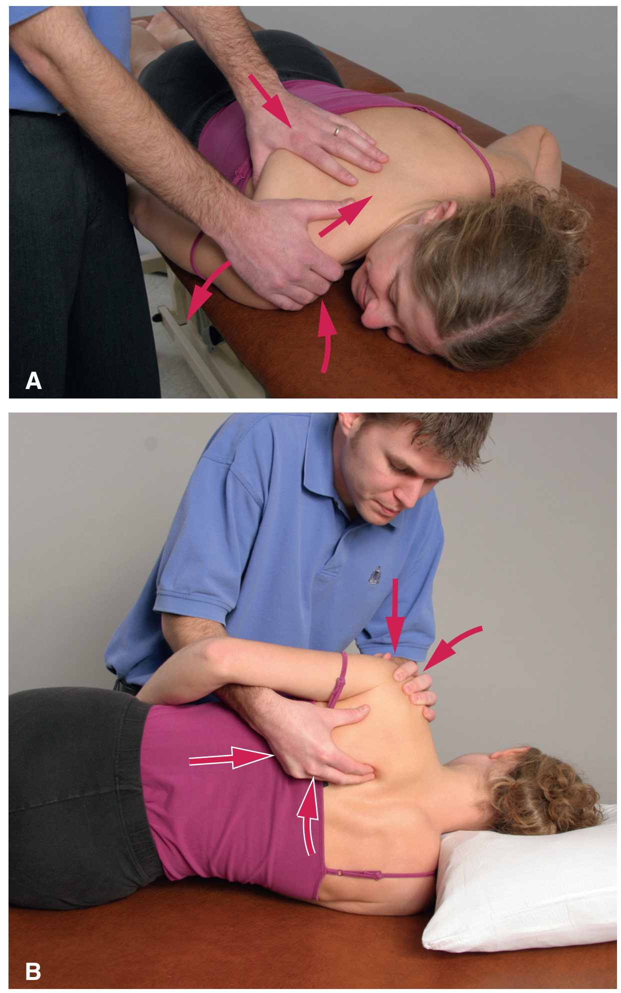

FIGURE 3.6 ROM of the scapula with the patient **(A)** prone and with the patient **(B)** side-lying.

Hand Placement and Procedure

- Cup the top hand over the acromion process and place the other hand around the inferior angle of the scapula.
- For elevation, depression, protraction, and retraction, the clavicle also moves as the scapular motions are directed at the acromion process.
- For rotation, direct the scapular motions at the inferior angle of the scapula while simultaneously pushing the acromion in the opposite direction to create a force couple turning effect.

Elbow: Flexion and Extension (Fig. 3.7)

VIDEO 3.3

Hand Placement and Procedure

Hand placement is the same as with shoulder flexion except the motion occurs at the elbow as it is flexed and extended.

NOTE: Control forearm supination and pronation with your fingers around the distal forearm. Perform elbow flexion and extension with the forearm pronated as well as supinated. The scapula should not tip forward when the elbow extends, as it disguises the true range.

FIGURE 3.7 Elbow **(A)** flexion and **(B)** extension with the forearm supinated.

Elongation of Two-Joint Biceps Brachii Muscle

To extend the shoulder beyond zero, position the patient's shoulder at the edge of the table when supine or position the patient prone lying, sitting, or standing.

Hand Placement and Procedure

- First, pronate the patient's forearm by grasping the wrist and extend the elbow while supporting it.
- Then, extend (hyperextend) the shoulder to the point of tissue resistance in the anterior arm region. At this point, full available lengthening of the two-joint muscle is reached.

Elongation of Two-Joint Long Head of the Triceps Brachii Muscle (Fig. 3.8)

When near-normal range of the triceps brachii muscle is available, the patient must be sitting or standing to reach the full ROM. With marked limitation in muscle range, ROM can be performed in the supine position.

Hand Placement and Procedure

- First, fully flex the patient's elbow with one hand on the distal forearm.
- Then, flex the shoulder by lifting up on the humerus with the other hand under the elbow.
- Full available range is reached when discomfort is experienced in the posterior arm region.

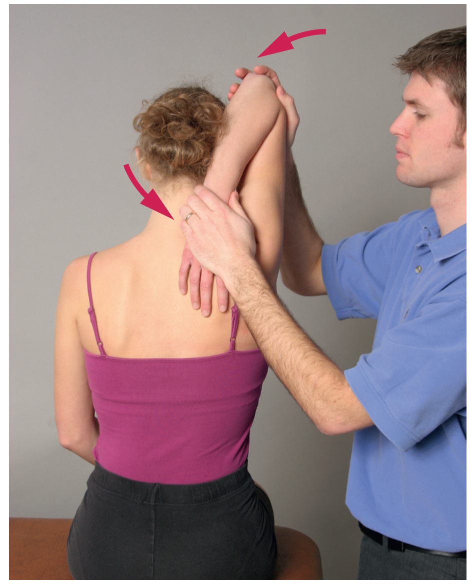

FIGURE 3.8 End ROM for the long head of the triceps brachii muscle.

Forearm: Pronation and Supination (Fig. 3.9)

Hand Placement and Procedure

- Grasp the patient's wrist, supporting the hand with the index finger and placing the thumb and the rest of the fingers on either side of the distal forearm.
- Stabilize the elbow with the other hand.
- The motion is a rolling of the radius around the ulna at the distal radius.

Alternate Hand Placement

Sandwich the patient's distal forearm between the palms of both hands.

NOTE: Pronation and supination should be performed with the elbow both flexed and extended.

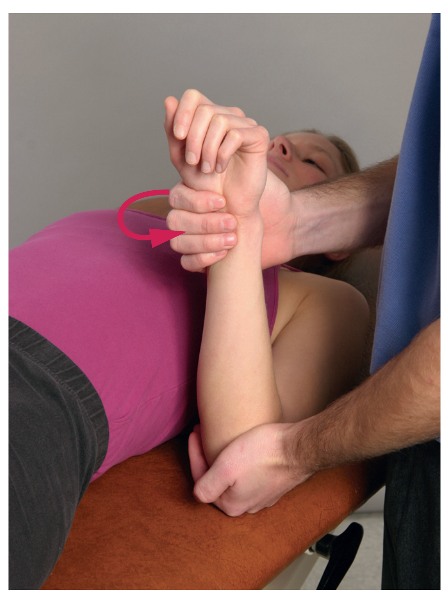

FIGURE 3.9 Pronation of the forearm.

PRECAUTION: Do not stress the wrist by twisting the hand; control the pronation and supination motion by moving the radius around the ulna.

Wrist: Flexion (Palmar Flexion) and Extension (Dorsiflexion); Radial (Abduction) and Ulnar (Adduction) Deviation (Fig. 3.10) VIDEO 3.4

Hand Placement and Procedure

For all wrist motions, grasp the patient's hand just distal to the joint with one hand and stabilize the forearm with your other hand.

NOTE: The range of the extrinsic muscles to the fingers affects the range at the wrist if tension is placed on the tendons as they cross into the fingers. To obtain full range of the wrist joint, allow the fingers to move freely as you move the wrist.

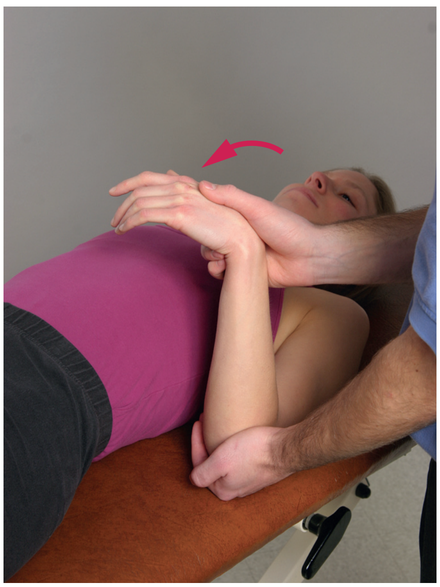

FIGURE 3.10 ROM at the wrist. Shown is wrist flexion; note that the fingers are free to move in response to passive tension in the extrinsic tendons.

Hand: Cupping and Flattening the Arch of the Hand at the Carpometacarpal and Intermetacarpal Joints (Fig. 3.11)

Hand Placement and Procedure

- Face the patient's hand; place the fingers of both of your hands in the palms of the patient's hand and your thenar eminences on the posterior aspect.
- Roll the metacarpals palmarward to increase the arch and dorsalward to flatten it.

Alternate Hand Placement

One hand is placed on the posterior aspect of the patient's hand, with the fingers and thumb cupping the metacarpals.

FIGURE 3.11 ROM to the arch of the hand.

NOTE: Extension and abduction of the thumb at the carpometacarpal joint are important for maintaining the web space for functional movement of the hand. Isolated flexion-extension and abduction-adduction ROM of this joint should be performed by moving the first metacarpal while stabilizing the trapezium.

Joints of the Thumb and Fingers: Flexion and Extension and Abduction and Adduction (Fig. 3.12) VIDEO 3.5

The joints of the thumbs and fingers include the metacarpophalangeal and interphalangeal joints.

Hand Placement and Procedure

- Depending on the position of the patient, stabilize the forearm and hand on the bed or table or against your body.

FIGURE 3.12 ROM to the metacarpophalangeal joint of the thumb.

- Move each joint of the patient's hand individually by stabilizing the proximal bone with the index finger and thumb of one hand and moving the distal bone with the index finger and thumb of the other hand.

Alternate Procedure

Several joints can be moved simultaneously if proper stabilization is provided. Example: To move all the metacarpophalangeal joints of digits 2 through 5, stabilize the metacarpals with one hand and move all the proximal phalanges with the other hand.

NOTE: To accomplish full joint ROM, do not place tension on the extrinsic muscles going to the fingers. Tension on the muscles can be relieved by altering the wrist position as the fingers are moved.

Elongation of Extrinsic Muscles of the Wrist and Hand: Flexor and Extensor Digitorum Muscles (Fig. 3.13)

General Technique

Hand Placement and Procedure

- First, move the distal interphalangeal joint and stabilize it; then move the proximal interphalangeal joint.
- Hold both these joints at the end of their range; then move the metacarpophalangeal joint to the end of the available range.
- Stabilize all the finger joints and begin to extend the wrist. When the patient feels discomfort in the forearm, the muscles are fully elongated.

NOTE: Motion is initiated in the distal-most joint of each digit in order to minimize compression of the small joints. Full joint ROM will not be possible when the extrinsic muscles are elongated.

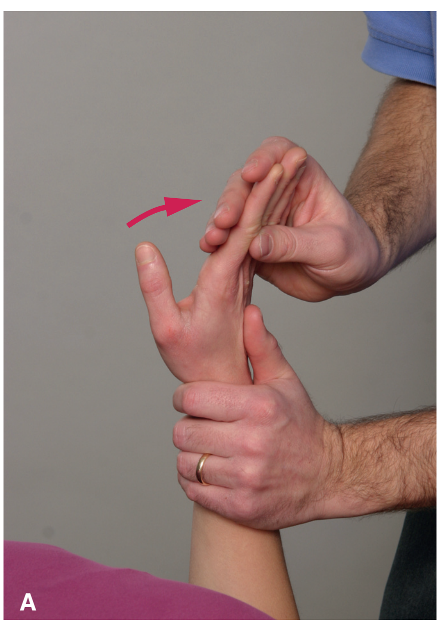

FIGURE 3.13 End of range for the extrinsic finger **(A)** flexors and

FIGURE 3.13 (B) extensors.

Lower Extremity

Combined Hip and Knee: Flexion and Extension (Fig. 3.14) VIDEO 3.6

To reach full range of hip flexion, the knee must also be flexed to release tension on the hamstring muscle group. To reach full range of knee flexion, the hip must be flexed to release tension on the rectus femoris muscle.

Hand Placement and Procedure

- Support and lift the patient's leg with the palm and fingers of the top hand under the patient's knee and the lower hand under the heel.
- As the knee flexes full range, swing the fingers to the side of the thigh.

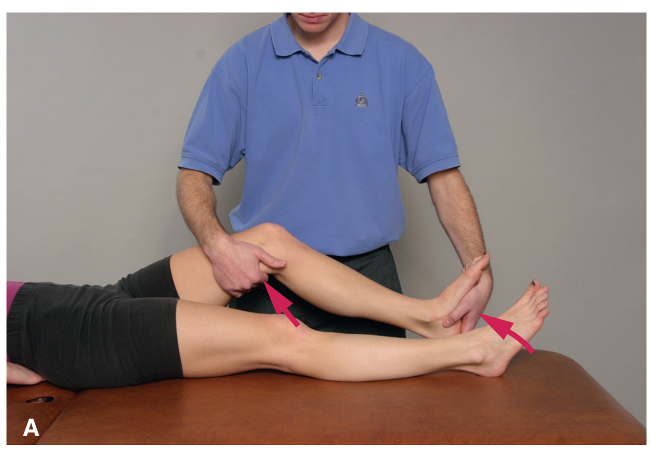

FIGURE 3.14 (A) Initiating and

FIGURE 3.14—cont'd (B) completing combined hip and knee flexion.

FIGURE 3.16 ROM to the hamstring muscle group.

Hip: Extension (Hyperextension) (Fig. 3.15)

Prone or side-lying must be used if the patient has near-normal or normal motion.

Hand Placement and Procedure

- If the patient is prone, lift the thigh with the bottom hand under the patient's knee; stabilize the pelvis with the top hand or arm.
- If the patient is side-lying, bring the bottom hand under the thigh and place the hand on the anterior surface; stabilize the pelvis with the top hand. For full range of hip extension, do not flex the knee full range, as the two-joint rectus femoris would then restrict the range.

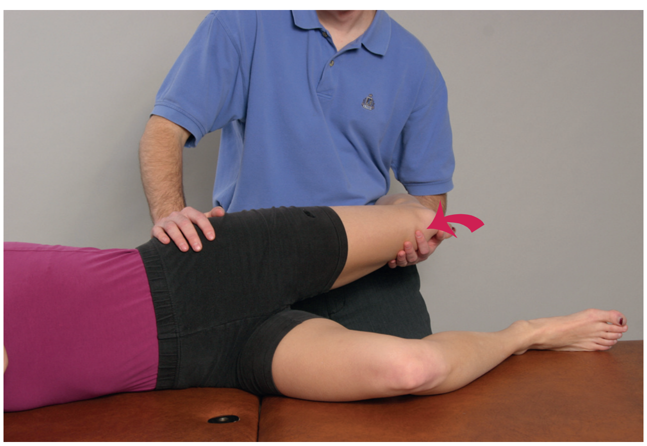

FIGURE 3.15 Hip extension with the patient side-lying.

Elongation of the Two-Joint Hamstring Muscle Group (Fig. 3.16)

Hand Placement and Procedure

- Place the lower hand under the patient's heel and the upper hand across the anterior aspect of the patient's knee.
- Keep the knee in extension as the hip is flexed.
- If the knee requires support, cradle the patient's leg in your lower arm with your elbow flexed under the calf and your hand across the anterior aspect of the patient's knee. The other hand provides support or stabilization where needed.

NOTE: If the hamstrings are so tight as to limit the knee from going into extension, the available range of the muscle is reached simply by extending the knee as far as the muscle allows and not moving the hip.

Elongation of the Two-Joint Rectus Femoris Muscle

Position the patient supine with knee flexed over the edge of the treatment table or position prone.

Hand Placement and Procedure

- When supine, stabilize the lumbar spine by flexing the hip and knee of the opposite lower extremity and placing the foot on the treatment table (hook lying).
- When prone, stabilize the pelvis with the top hand (see Fig. 4.31)
- Flex the patient's knee until tissue resistance is felt in the anterior thigh, which means the full available range is reached.

Hip: Abduction and Adduction (Fig. 3.17)

Hand Placement and Procedure

- Support the patient's leg with the upper hand under the knee and the lower hand under the ankle.
- For full range of adduction, the opposite leg needs to be in a partially abducted position.
- Keep the patient's hip and knee in extension and neutral to rotation as abduction and adduction are performed.

FIGURE 3.17 Abduction of the hip, maintaining the hip in extension and neutral to rotation.

Hip: Internal (Medial) and External (Lateral) Rotation

Hand Placement and Procedure with the Hip and Knee Extended

- Grasp just proximal to the patient's knee with the top hand and just proximal to the ankle with the bottom hand.
- Roll the thigh inward and outward.

Hand Placement and Procedure for Rotation with the Hip and Knee Flexed (Fig. 3.18)

- Flex the patient's hip and knee to 90°; support the knee with the top hand.
- If the knee is unstable, cradle the thigh and support the proximal calf and knee with the bottom hand.
- Rotate the femur by moving the leg like a pendulum.
- This hand placement provides some support to the knee but should be used with caution if there is knee instability.

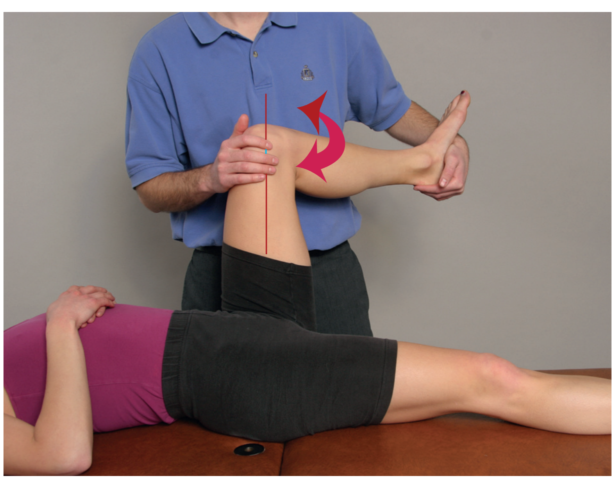

FIGURE 3.18 Rotation of the hip with the hip positioned in 90° of flexion.

Ankle: Dorsiflexion (Fig. 3.19) VIDEO 3.7

Hand Placement and Procedure)

- Stabilize around the malleoli with the top hand.
- Cup the patient's heel with the bottom hand and place the forearm along the bottom of the foot.
- Pull the calcaneus distalward with the thumb and fingers while pushing upward with the forearm.

NOTE: If the knee is flexed, full range of the ankle joint can be obtained. If the knee is extended, the lengthened range of the two-joint gastrocnemius muscle can be obtained, but the gastrocnemius limits full range of dorsiflexion. Apply dorsiflexion in both positions of the knee to provide range to both the joint and the muscle.

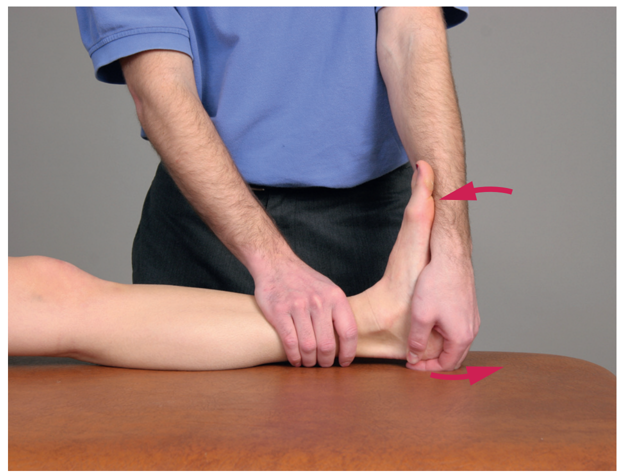

FIGURE 3.19 Dorsiflexion of the ankle.

Ankle: Plantarflexion

Hand Placement and Procedure

- Support the heel with the bottom hand.
- Place the top hand on the dorsum of the foot and push it into plantarflexion.

NOTE: In bed-bound patients, the ankle tends to assume a plantarflexed position from the weight of the blankets and the pull of gravity, so this motion may not need to be performed.

Subtalar (Lower Ankle) Joint: Inversion and Eversion (Fig. 3.20)

Hand Placement and Procedure

- Using the bottom hand, place the thumb medial and the fingers lateral to the joint on either side of the heel.
- Turn the heel inward and outward.

NOTE: Supination of the foot may be combined with inversion, and pronation may be combined with eversion.

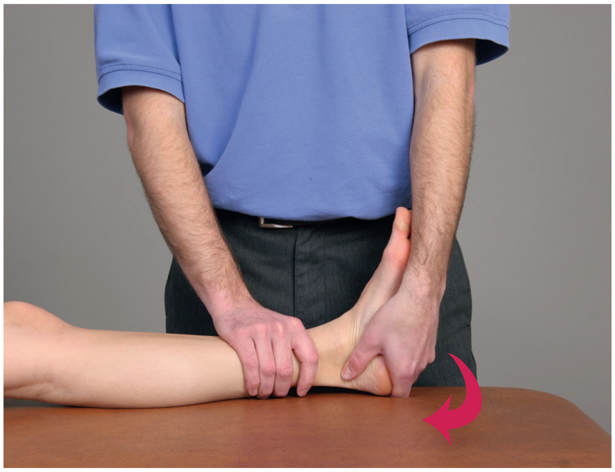

FIGURE 3.20 Inversion of the subtalar joint.

Transverse Tarsal Joint

Hand Placement and Procedure

- Stabilize the patient's talus and calcaneus with one hand.
- With the other hand, grasp around the navicular and cuboid.
- Gently rotate the midfoot by lifting and lowering the arch.

Joints of the Toes: Flexion and Extension and Abduction and Adduction (Metatarsophalangeal and Interphalangeal Joints) (Fig. 3.21)

Hand Placement and Procedure

- Stabilize the bone proximal to the joint that is to be moved with one hand, and move the distal bone with the other hand.
- The technique is the same as for ROM of the fingers.
- Several joints of the toes can be moved simultaneously if care is taken not to stress any structure.

FIGURE 3.21 Extension of the metatarsophalangeal joint of the large toe.

Cervical Spine VIDEO 3.8

Stand at the end of the treatment table, securely grasp the patient's head by placing both hands under the occipital region.

Flexion (Forward Bending) (Fig. 3.22A)

Procedure

- Lift the head as though it were nodding (chin toward larynx) to flex the head on the neck.
- Once full nodding is complete, continue to flex the cervical spine and lift the head toward the sternum.

FIGURE 3.22 Cervical **(A)** flexion and

Extension (Backward Bending or Hyperextension)

Procedure

Tip the head backward.

NOTE: If the patient is supine, only the head and upper cervical spine can be extended; the head must clear the end of the table to extend the entire cervical spine. The patient may also be prone or sitting.

Lateral Flexion (Side Bending) and Rotation (Fig. 3.22B)

Procedure

Maintain the cervical spine neutral to flexion and extension as you direct the head and neck into side bending (approximate the ear toward the shoulder) and rotation (rotate from side to side).

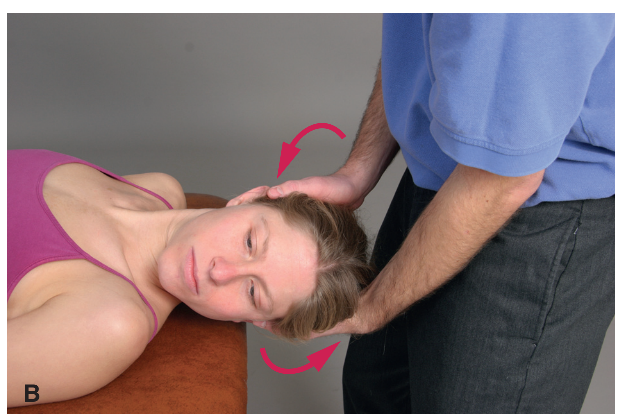

FIGURE 3.22 **(B)** rotation.

Lumbar Spine VIDEO 3.9

Flexion (Fig. 3.23)

Hand Placement and Procedure

- Bring both of the patient's knees to the chest by lifting under the knees (hip and knee flexion).
- Flexion of the spine occurs as the hips are flexed full range and the pelvis starts to rotate posteriorly.
- Greater range of flexion can be obtained by lifting under the patient's sacrum with the lower hand.

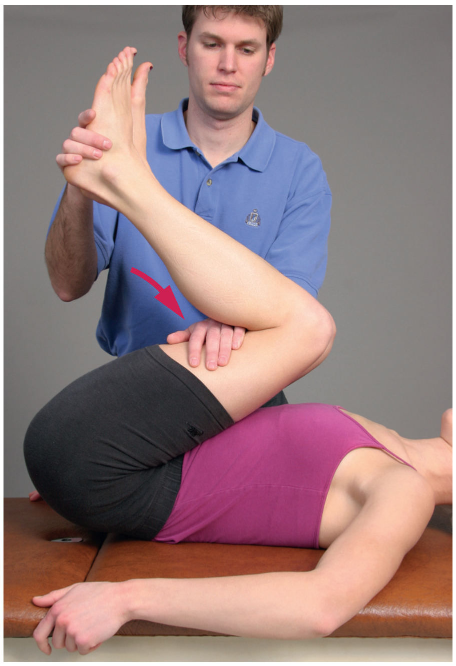

FIGURE 3.23 Lumbar flexion is achieved by bringing the patient's hips into flexion until the pelvis rotates posteriorly.

Extension

Position the patient prone for full extension (hyperextension).

Hand Placement and Procedure

With hands under the thighs, lift the thighs upward until the pelvis rotates anteriorly and the lumbar spine extends.

Rotation (Fig. 3.24)

Position the patient in hook-lying with hips and knees flexed and feet resting on the table.

Hand Placement and Procedure

- Push both of the patient's knees laterally in one direction until the pelvis on the opposite side comes up off the treatment table.
- Stabilize the patient's thorax with the top hand.
- Repeat in the opposite direction.

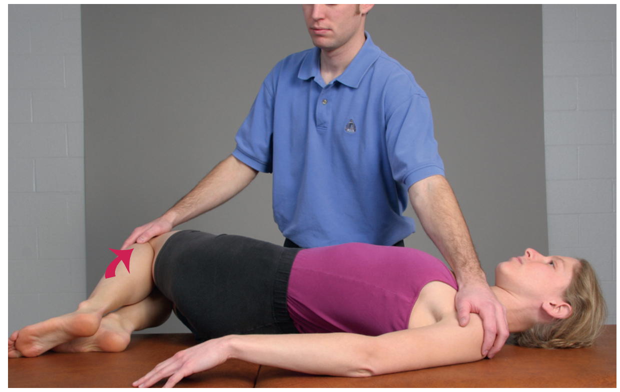

FIGURE 3.24 Rotation of the lumbar spine results when the thorax is stabilized and the pelvis lifts off the table as far as allowed.

CLINICAL TIP

Effective and efficient ROM can be administered by combining several joint motions that transect several planes resulting in oblique, functional, or diagonal patterns.

- For example, wrist flexion may be combined with ulnar deviation, or shoulder flexion may be combined with abduction and lateral rotation.
- Use patterns that mimic functional activities such as moving hand behind head as in combing hair—add rotation of the neck. (See also Box 3.3 at end of chapter.)
- Proprioceptive neuromuscular facilitation (PNF) patterns of movement may be effectively used for PROM, AROM, or A-AROM techniques. (See Chapter 6 for descriptions of these patterns.)

Self-Assisted ROM

Patient involvement in self-care should begin as soon as the individual is able to understand and learn what to do. Even with weakness or paralysis, the patient can learn how to move the involved part and be instructed in the importance of movement within safe parameters. After surgery or traumatic injury, self-assisted ROM (S-AROM) is used to protect the healing tissues when more intensive muscle contraction is contraindicated. A variety of devices as well as use of a normal extremity may be used to meet the goals of PROM or A-AROM. Incorporation of S-AROM then becomes a part of the home exercise program (Box 3.2).

Self-Assistance

With cases of unilateral weakness or paralysis or during early stages of recovery after trauma or surgery, the patient can be taught to use the uninvolved extremity to move the involved

BOX 3.2 Self-Assisted Range of Motion Techniques

Forms of Self-Assisted ROM
- Manual
- Equipment
  - Wand or T-bar
  - Finger ladder, wall climbing, ball rolling
  - Pulleys
  - Skate board/powder board
  - Reciprocal exercise devices

Guidelines for Teaching Self-Assisted ROM
- Educate the patient on the value of the motion.
- Teach the patient correct body alignment and stabilization.
- Observe patient performance and correct any substitute or unsafe motions.
- If equipment is used, be sure all hazards are eliminated for application to be safe.
- Provide drawings and clear guidelines for number of repetitions and frequency.

Review the exercises at a follow-up session. Modify or progress the exercise program based on the patient response and treatment plan for meeting the outcome goals.

extremity through ranges of motion. These exercises may be done supine, sitting, or standing. The effects of gravity change with patient positioning, so when lifting the part against gravity, gravity provides a resistive force against the prime motion, and therefore, the prime mover requires assistance. When the extremity moves downward, gravity causes the motion, and the antagonists need assistance to control the motion eccentrically.

Arm and Forearm

Instruct the patient to reach across the body with the uninvolved (or assisting) extremity and grasp the involved extremity around the wrist, supporting the wrist and hand (Fig. 3.25).

- ***Shoulder flexion and extension.*** The patient lifts the involved extremity over the head and returns it to the side (Fig. 3.25).
- ***Shoulder horizontal abduction and adduction.*** Beginning with the arm abducted 90°, the patient pulls the extremity across the chest and returns it to the side.
- ***Shoulder rotation.*** Beginning with the arm at the patient's side in slight abduction or abducted 90° and elbow flexed 90°, the patient rotates the forearm with the uninvolved extremity (Fig. 3.26). It is important to emphasize rotating the humerus, not merely flexing and extending the elbow.
- ***Elbow flexion and extension.*** The patient bends the elbow until the hand is near the shoulder and then moves the hand down toward the side of the leg.

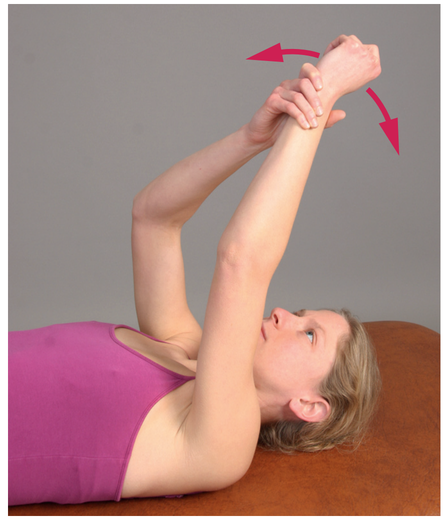

FIGURE 3.25 Patient giving self-assisted ROM to shoulder flexion and extension. Horizontal abduction and adduction can be applied with the same hand placement.

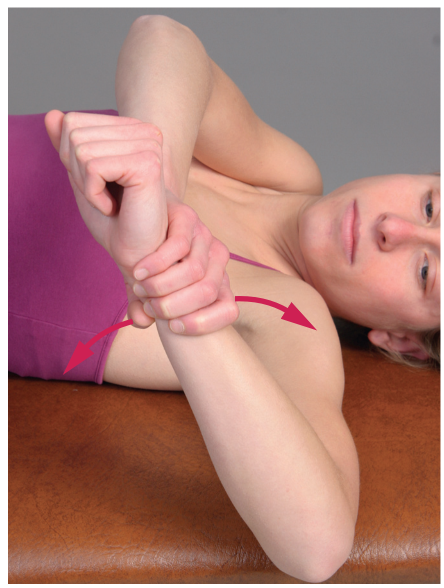

FIGURE 3.26 Arm position of patient for giving self-assisted ROM to internal and external rotation of shoulder.

- ***Pronation and supination of the forearm.*** Beginning with the forearm resting across the body, the patient rotates the radius around the ulna. Emphasize to the patient not to twist the hand at the wrist joint.

Wrist and Hand

The patient moves the uninvolved fingers to the dorsum of the hand and the thumb into the palm of the hand.

- ***Wrist flexion and extension and radial and ulnar deviation.*** The patient moves the wrist in all directions, applying no pressure against the fingers (Fig. 3.27).

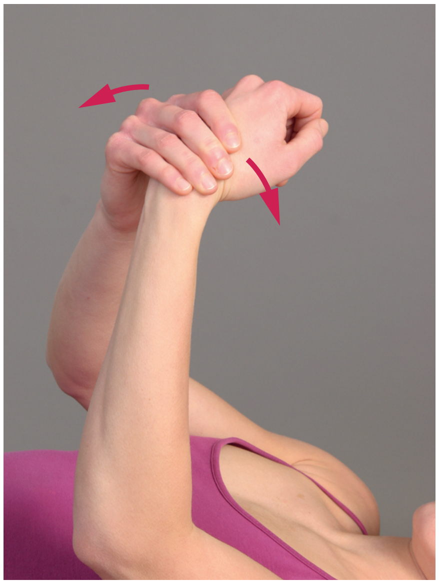

FIGURE 3.27 Patient applying self-assisted wrist flexion and extension with no pressure against the fingers.

- ***Finger flexion and extension.*** The patient uses the uninvolved thumb to extend the involved fingers and cups the normal fingers over the dorsum of the involved fingers to flex them (Fig. 3.28).

FIGURE 3.28 Patient applying self-assisted finger flexion and extension.

- ***Thumb flexion with opposition and extension with reposition.*** The patient cups the uninvolved fingers around the radial border of the thenar eminence of the involved thumb and places the uninvolved thumb along the palmar surface of the involved thumb to extend it (Fig. 3.29). To flex and oppose the thumb, the patient cups the normal hand around the dorsal surface of the involved hand and pushes the first metacarpal toward the little finger.

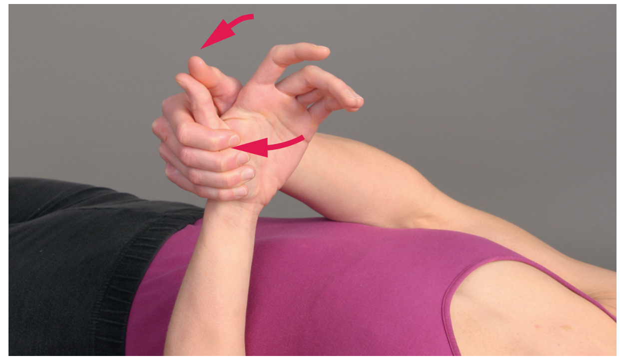

FIGURE 3.29 Patient applying self-assisted thumb extension.

Hip and Knee

- ***Hip and knee flexion.*** With the patient supine, instruct the patient to initiate the motion by lifting up the involved knee with a strap or belt under the involved knee (Fig. 3.30). The patient can then grasp the knee with one or both hands to bring the knee up toward the chest to complete the range. With the patient sitting, he or she may lift the thigh with the hands and flex the knee to the end of its available range.

FIGURE 3.30 Self-assisted flexion of the hip.

- ***Hip abduction and adduction.*** It is difficult for the weak patient to assist the lower extremities into abduction and adduction when supine, owing to the weight of the leg and the friction of the bed surface. It is necessary, though, for the individual to move a weak lower extremity from side to side for bed mobility. To practice this functional activity as an exercise, instruct the patient to slide the normal foot from the knee down to the ankle and then move the involved extremity from side-to-side. S-AROM can be performed sitting by using the hands to assist moving the thigh outward and inward.

- ***Combined hip abduction with external rotation.*** The patient is sitting on the floor or on a bed with the back supported and the involved hip and knee flexed with the foot resting on the surface. The knee is moved outward (toward the table/bed) and back inward, with assistance from the upper extremity (Fig. 3.31).

FIGURE 3.31 Self-assisted hip abduction and external rotation.

Ankle and Toes

- The patient sits with the involved extremity crossed over the uninvolved one so the distal leg rests on the normal knee. The uninvolved hand moves the involved ankle into dorsiflexion, plantarflexion, inversion, and eversion, and toe flexion and extension (Fig. 3.32).

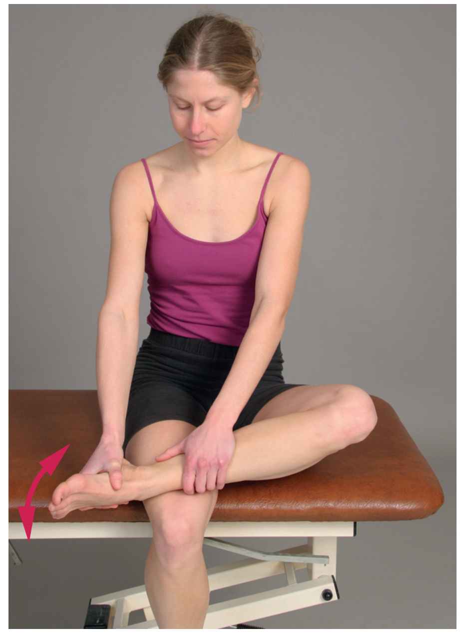

FIGURE 3.32 Position of patient and hand placement for self-assisted ankle and toe motions; shown is inversion and eversion.

Wand (T-Bar) Exercises

When a patient has voluntary muscle control in an involved upper extremity but needs guidance or motivation to complete the ROM in the shoulder or elbow, a wand (dowel rod, cane, wooden stick, T-bar, or similar object) can be used to provide assistance (Fig. 3.33).

The choice of position is based on the patient's level of function. Most of the techniques can be performed supine if maximum protection is needed. Sitting or standing requires greater control. Choice of position is also guided by the effects of gravity on the weak muscles. Initially, guide the patient through the proper motion for each activity to ensure that he or she does not use substitute motions. The patient grasps the wand with both hands, and the normal extremity guides and controls the motions.

- ***Shoulder flexion and return.*** The wand is grasped with the hands a shoulder-width apart. The wand is lifted forward and upward through the available range, with the elbows kept in extension if possible (Fig. 3.33A). Scapulohumeral motion should be smooth; do not allow scapular elevation or trunk movement.
- ***Shoulder horizontal abduction and adduction.*** The wand is lifted to 90° shoulder flexion. Keeping the elbows extended, the patient pushes and pulls the wand back and forth across the chest through the available range (Fig. 3.33B). Do not allow trunk rotation.
- ***Shoulder internal and external rotation.*** The patient's arms are at the sides, and the elbows are flexed 90°. Rotation of the arms is accomplished by moving the wand from side to side across the trunk while maintaining the elbows at the side (Fig. 3.33C). The rotation should occur in the humerus; do not allow elbow flexion and extension. To prevent substitute motions as well as provide a slight distraction force to the glenohumeral joint, a small towel roll may be placed in the axilla with instruction to the patient to "keep the roll in place."
- ***Shoulder internal and external rotation—alternate position.*** The patient's shoulders are abducted 90° and the elbows flexed 90°. For external rotation, the wand is moved toward the patient's head; for internal rotation, the wand is moved toward the waistline.
- ***Elbow flexion and extension.*** The patient's forearms may be pronated or supinated; the hands grasp the wand a shoulder-width apart. Instruct the patient to flex and extend the elbows.
- ***Shoulder hyperextension.*** The patient may be standing or prone. He or she places the wand behind the buttocks, grasps the wand with hands a shoulder-width apart, and

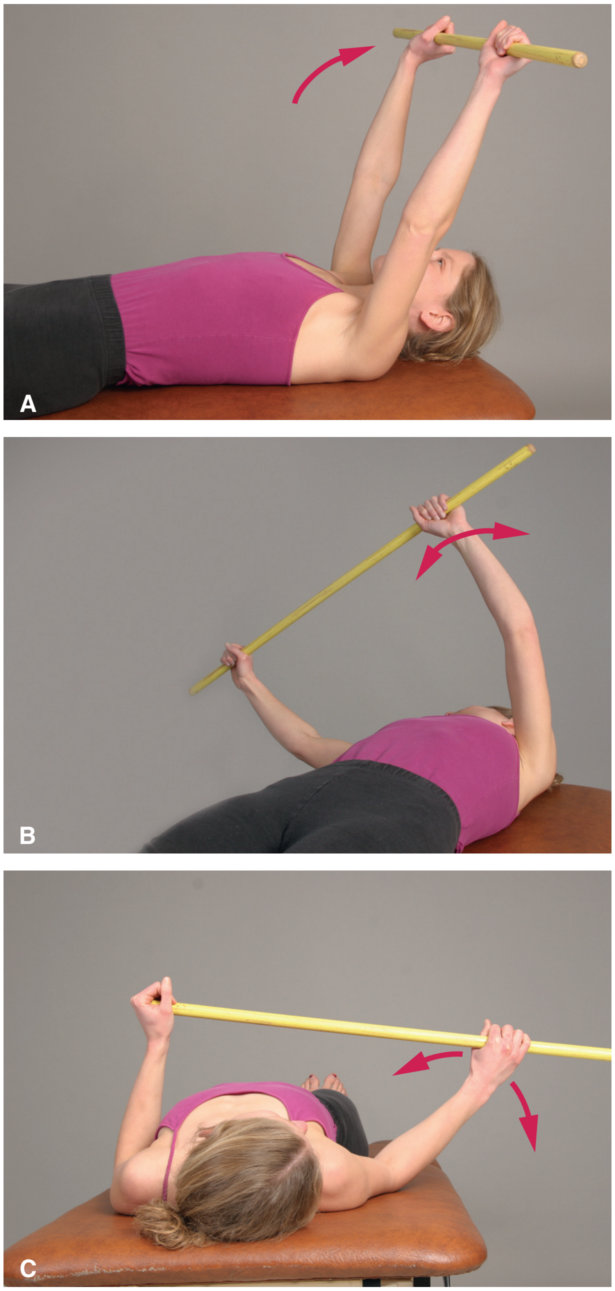

FIGURE 3.33 Patient using a wand for self-assisted shoulder (A) flexion, (B) horizontal abduction/adduction, and (C) rotation.

then lifts the wand backward away from the trunk. The patient should avoid trunk motion.

- ***Variations and combinations of movements.*** For example, the patient begins with the wand behind the buttocks and then moves the wand up the back to achieve scapular winging, shoulder internal rotation, and elbow flexion.

Wall Climbing

Wall climbing (or use of a device such as a finger ladder) can provide the patient with objective reinforcement and, therefore, motivation for performing shoulder ROM. Wall markings may also be used to provide visual feedback for the height reached. The arm may be moved into flexion or abduction (Fig. 3.34). The patient steps closer to the wall as the arm is elevated.

PRECAUTION: The patient must be taught the proper motions and not allowed to substitute with trunk side bending, toe raising, or shoulder shrugging.

FIGURE 3.34 Wall climbing for shoulder elevation.

Overhead Pulleys

If properly taught, pulley systems can be effectively used to assist an involved extremity in performing ROM. The pulley has been demonstrated to utilize significantly more muscle activity than therapist-assisted ROM and continuous passive motion machines (described later in the chapter), so this form of assistance should be used only when muscle activity is desired.[6]

For home use, a single pulley may be attached to a strap that is held in place by closing the strap in a door. A pulley may also be attached to an overhead bar or affixed to the ceiling. The patient should be set up so the pulley is directly over the joint that is moving or so the line of pull is effectively moving the extremity and not just compressing the joint surfaces together. The patient may be sitting, standing, or supine.

Shoulder ROM (Fig. 3.35)

Instruct the patient to hold one handle in each hand, and with the normal hand, pull the rope and lift the involved extremity forward (flexion), out to the side (abduction), or in the plane of the scapula (scaption is 30° forward of the frontal plane). The patient should not shrug the shoulder

FIGURE 3.35 Use of overhead pulleys to assist shoulder elevation.

(scapular elevation) or lean the trunk. Guide and instruct the patient so there is smooth motion.

PRECAUTION: Assistive pulley activities for the shoulder are easily misused by the patient, resulting in compression of the humerus against the acromion process. Continual compression leads to pain and decreased function. Proper patient selection and appropriate instruction can avoid this problem. If a patient cannot learn to use the pulley with proper shoulder mechanics, these exercises should not be performed. Discontinue this activity if there is increased pain or decreased mobility.

Elbow Flexion

With the arm stabilized along the side of the trunk, the patient lifts the forearm and bends the elbow.

Skate Board/Powder Board

Use of a friction-free surface may encourage movement without the resistance of gravity or friction. If available, a skate with rollers may be used. Other methods include using powder on the surface or placing a towel under the extremity so it can slide along the smooth surface of the board. Any motion can be done, but most common are abduction/adduction of the hip while supine and horizontal abduction/adduction of the shoulder while sitting.

Reciprocal Exercise Unit

Several devices, such as a bicycle, upper body or lower body ergometer, or a reciprocal exercise unit, can be set up to provide some flexion and extension to an involved extremity using the strength of the normal extremity. Movable devices that can be attached to a patient's bed, wheelchair, or standard chair are available. The circumference of motion as well as excursion of the extremities can be adjusted. A reciprocal exercise unit has additional exercise benefits in that it can be used for reciprocal patterning, endurance training, and strengthening by changing the parameters of the exercise and monitoring the heart rate and fatigue. (See Chapter 6 for principles of resistance exercise and Chapter 7 for principles of aerobic exercise.)

Continuous Passive Motion

Continuous passive motion (CPM) refers to passive motion performed by a mechanical device that moves a joint slowly and continuously through a controlled ROM. The mechanical devices that exist for nearly every joint in the body (Fig. 3.36) were developed as a result of research by Robert Salter, who demonstrated that continual passive motion has beneficial

A

B

FIGURE 3.36 Continuous Motion Devices for **(A)** the shoulder and **(B)** the knee.

healing effects on diseased or injured joint structures and soft tissues in animal and clinical studies.[20-25] Since the development of CPM, many studies have been done to determine the parameters of application; but because the devices are used for many conditions and studies have used various protocols with varying research designs, no definitive delineation has been established.[4,13,17]

Benefits of CPM

CPM has been reported to be effective in lessening the negative effects of joint immobilization in conditions such as arthritis, contractures, and intra-articular fractures; it has also improved the recovery rate and ROM after a variety of surgical procedures.[13,17,20-25,27] Basic research and clinical studies reported by Salter have demonstrated the effectiveness of CPM in a number of areas.

- Prevents development of adhesions and contractures and thus joint stiffness
- Provides a stimulating effect on the healing of tendons and ligaments
- Enhances healing of incisions over the moving joint
- Increases synovial fluid lubrication of the joint and thus increases the rate of intra-articular cartilage healing and regeneration
- Prevents the degrading effects of immobilization
- Provides a quicker return of ROM
- Decreases postoperative pain

FOCUS ON EVIDENCE

Various studies have compared short and long-term outcomes of CPM use after various types of surgery using various parameters as well as CPM with other methods of early movement and positioning.[1,5,6,11,12,17-19,28,30] Some studies have shown no significant difference between patients undergoing CPM and those undergoing PROM or other forms of early motion.[5,11,12,19,29] Many studies support the short-term benefits of CPM use after surgery in that patients gain ROM more quickly and, therefore, may experience earlier discharge from the hospital when CPM is used compared with other forms of intervention. However, long-term functional gains are reported to be no different from those in patients who underwent other forms of early motion.[4,28,30]

The authors of a Cochrane Review of 14 randomized controlled trials in which CPM was used following total knee arthroplasty summarized that for patients who had CPM combined with physical therapy, there was a significant increase in active knee flexion and decrease in length of hospital stay as well as a decreased need for post-operative manipulation compared to those receiving physical therapy alone. There was no significant difference in passive knee flexion or passive or active knee extension.[14a]

Some studies have identified detrimental effects, such as the need for greater analgesic intervention and increased postoperative blood drainage, when using CPM[18,29] in contrast to claims that CPM decreases postoperative pain and postoperative complications.[21-25,27] Cost-effectiveness of the CPM equipment, patient compliance, utilization and supervision of equipment by trained personnel, length of hospital stay, speed of recovery, and determination of appropriate patient populations become issues to consider when making the choice of whether or not to utilize CPM devices.[12,15]

General Guidelines for CPM

General guidelines for CPM are as follows[3,4,10,13,14,20,25]:

1. The device may be applied to the involved extremity immediately after surgery while the patient is still under anesthesia or as soon as possible if bulky dressings prevent early motion.
2. The arc of motion for the joint is determined. Often a low arc of 20° to 30° is used initially and progressed 10° to 15° per day as tolerated. The portion of the range used initially is based on the range available and patient tolerance. One study looked at accelerating the range of knee flexion after total knee arthroplasty and found that a greater range and earlier discharge were attained for that group of patients,[30] although there was no difference between the groups at 4 weeks.
3. The rate of motion is determined; usually 1 cycle/45 sec or 2 min is well tolerated.
4. The amount of time on the CPM machine varies for different protocols—anywhere from continuous for 24 hours to continuous for 1 hour three times a day.[10,14,25] The longer periods of time per day reportedly result in a shorter hospital stay, fewer postoperative complications, and greater ROM at discharge,[10] although no significant difference was found in a study comparing CPM for 5 hr/day with CPM for 20 hr/day.[3] A recent study compared short-duration CPM (3 to 5 hr/day) with long-duration CPM (10 to 12 hr/day) and found that patient compliance and the most gained range occurred with a CPM duration of 4 to 8 hours.[4]
5. Physical therapy treatments are usually initiated during periods when the patient is not on CPM, including active-assistive and muscle-setting exercises. It is important that patients learn to use and develop motor control of the ROM as motion improves.
6. The duration minimum for CPM is usually less than 1 week or when a satisfactory range of motion is reached. Because CPM devices are portable, home use is possible in cases in which the therapist or physician deems additional time would be beneficial. In these cases, the patient, a family member, or a caregiver is instructed in proper application.

7. CPM machines are designed to be adjustable, easily controlled, versatile, and portable. Some are battery operated (with rechargeable batteries) to allow the individual to wear the device for up to 8 hours while functioning with daily activities.

ROM Through Functional Patterns

To accomplish motion through functional patterns, first determine what pattern of movement is desired and then move the extremity through that pattern using manual assistance, mechanical assistance if it is appropriate, or self-assistance from the patient. Functional patterning can be beneficial in initiating the teaching of ADL and instrumental activities of daily living (IADL) as well as in instructing patients with visual impairments in functional activities. Utilizing functional patterns helps the patient recognize the purpose and value of ROM exercises and develop motor patterns that can be used in daily activities as strength and endurance improves. Box 3.3 identifies some examples and the basic motions that are utilized. When the patient no longer requires assistance to perform the pattern safely and correctly, the activity is incorporated into his or her daily activities so motor learning is reinforced and the motion becomes functional.

BOX 3.3 Functional Range of Motion Activities

Early ROM training for functional upper extremity and neck patterns may include activities such as:

- Grasping an eating utensil; utilizing finger extension and flexion
- Eating (hand to mouth); utilizing elbow flexion and forearm supination and some shoulder flexion, abduction, and lateral rotation
- Reaching to various shelf heights; utilizing shoulder flexion and elbow extension
- Brushing or combing back of hair; utilizing shoulder abduction and lateral rotation, elbow flexion, and cervical rotation
- Holding a phone to the ear; shoulder lateral rotation, forearm supination, and cervical side bend
- Donning or doffing a shirt or jacket; utilizing shoulder extension, lateral rotation, elbow flexion and extension
- Reaching out a car window to an ATM machine; utilizing shoulder abduction, lateral rotation, elbow extension, and some lateral bending of the trunk

Early ROM training for functional lower extremity and trunk patterns may include activities such as:

- Going from supine to sitting at the side of a bed; utilizing hip abduction and adduction followed by hip and knee flexion
- Standing up/sitting down and walking; utilizing hip and knee flexion and extension, ankle dorsi and plantarflexion, and some hip rotation
- Putting on socks and shoes; utilizing hip external rotation and abduction, knee flexion and ankle dorsi and plantarflexion, and trunk flexion

Independent Learning Activities

Critical Thinking and Discussion

1. Analyze a variety of functional activities, such as grooming, dressing, and bathing, and determine the functional ranges needed to perform each task.
2. Look at the effects of gravity or other forces on the ROM for each activity in #1. If you had a patient who was unable to do the activity because of an inability to control the range needed, determine how you would establish an exercise program to begin preparing the individual to develop the desired function.

Laboratory Practice

1. Perform PROM of the upper and lower extremities with your partner placed in the following positions: prone, side-lying, sitting.
   a. What are the advantages and disadvantages of each of the positions for some of the ranges, such as shoulder and hip extension, knee flexion with the hip extended, rotation of the hip?
   b. Progress the PROM to A-AROM and AROM and determine the effects of gravity and the effort required in these positions compared to that in the supine position.
2. Compare the ROMs of the hip, knee, and ankle when each of the two joint muscles is elongated over its respective joint versus when each of the muscles is slack.

CHAPTER

4

Stretching for Impaired Mobility

The term *mobility* can be described based on two different but interrelated parameters. It is often defined as the ability of structures or segments of the body to move or be moved to allow the presence of range of motion for functional activities *(functional ROM)*.[2] It can also be defined as the ability of an individual to initiate, control, or sustain active movements of the body to perform simple to complex motor skills *(functional mobility)*.[42,124] Mobility, as it relates to functional ROM, is associated with joint integrity as well as the *flexibility* (i.e., extensibility of soft tissues that cross or surround joints—muscles, tendons, fascia, joint capsules, ligaments, nerves, blood vessels, skin), which are necessary for unrestricted, pain-free movements of the body during functional tasks of daily living. The ROM needed for the performance of functional activities does not necessarily mean full or "normal" ROM.

Sufficient mobility of soft tissues and ROM of joints must be supported by a requisite level of muscle strength and endurance and neuromuscular control to allow the body to accommodate to imposed stresses placed upon it during functional movement and, thus, to enable an individual to be functionally mobile. Moreover, soft tissue mobility, neuromuscular control, and muscular endurance and strength consistent with demand are thought to be an important factor in the prevention of injury or re-injury of the musculoskeletal system.[62,72,76,81,128,139,169]

Hypomobility (restricted motion) caused by adaptive shortening of soft tissues can occur as the result of many

disorders or situations. Factors include: (1) prolonged immobilization of a body segment; (2) sedentary lifestyle; (3) postural malalignment and muscle imbalances; (4) impaired muscle performance (weakness) associated with an array of musculoskeletal or neuromuscular disorders; (5) tissue trauma resulting in inflammation and pain; and (6) congenital or acquired deformities. Any factor that limits mobility—that is, causes decreased extensibility of soft tissues—may also impair muscular performance.[87] Hypomobility, in turn, can lead to activity limitations (functional limitations) and participation restrictions (disability) in a person's life.[9,20]

Just as strength and endurance exercises are essential interventions to improve impaired muscle performance or reduce the risk of injury, stretching interventions become an integral component of an individualized rehabilitation program when restricted mobility adversely affects function and increases the risk of injury. Stretching exercises also are considered an important element of fitness and sport-specific conditioning programs designed to promote wellness and reduce the risk of injury or re-injury.[62,128,139,169] *Stretching* is a general term used to describe any therapeutic maneuver designed to *increase* the extensibility of soft tissues, thereby improving flexibility and ROM by elongating (lengthening) structures that have adaptively shortened and have become hypomobile over time.[75,165]

Only through a systematic examination, evaluation, and diagnosis of a patient's presenting problems can a therapist determine what structures are restricting motion and if, when, and what types of stretching procedures are indicated. Early in the rehabilitation process, manual stretching and joint mobilization/manipulation, which involve direct, "hands-on" intervention by a practitioner, may be the most appropriate techniques. Later, self-stretching exercises performed independently by a patient after careful instruction and close supervision may be a more suitable intervention. In some situations, the use of a mechanical stretching device is indicated, particularly when manual therapies have been ineffective. Regardless of the types of stretching procedures selected for an exercise program, if the gain in ROM is to become permanent, it must be complemented by an appropriate level of strength and endurance and used on a regular basis in functional activities.

The stretching interventions described in this chapter are designed to improve the extensibility of the contractile and noncontractile components of muscle-tendon units and periarticular structures. The efficacy of these interventions is explored throughout the chapter. In addition to the stretching procedures for the extremities illustrated in this chapter, self-stretching exercises for each region of the body are described and illustrated in Chapters 16 through 22. Joint mobilization procedures for extremity joints are described and illustrated in Chapter 5 and for the temporomandibular joints, ribs, and sacrum in Chapter 15. Spinal mobilization and manipulation techniques are presented in Chapter 16.

Definition of Terms Associated with Mobility and Stretching

Flexibility

Flexibility is the ability to move a single joint or series of joints smoothly and easily through an unrestricted, pain-free ROM.[87,109] Muscle length in conjunction with joint integrity and the extensibility of periarticular soft tissues determine flexibility.[2] Flexibility is related to the extensibility of muscle-tendon units that cross a joint, based on their ability to relax or deform and yield to a stretch force. The arthrokinematics of the moving joint (the ability of the joint surfaces to roll and slide) as well as the ability of periarticular connective tissues to deform also affect joint ROM and an individual's overall flexibility.

Dynamic and Passive Flexibility

Dynamic flexibility. This form of flexibility, also referred to as active mobility or active ROM, is the degree to which an active muscle contraction moves a body segment through the available ROM of a joint. It is dependent on the degree to which a joint can be moved by a muscle contraction and the amount of tissue resistance met during the active movement.

Passive flexibility. This aspect of flexibility, also referred to as passive mobility or passive ROM, is the degree to which a body segment can be passively moved through the available ROM and is dependent on the extensibility of muscles and connective tissues that cross and surround a joint. Passive flexibility is a prerequisite for—but does not ensure—dynamic flexibility.

Hypomobility

Hypomobility refers to decreased mobility or restricted motion. A wide range of pathological processes can restrict movement and impair mobility. There are many factors that may contribute to hypomobility and stiffness of soft tissues, the potential loss of ROM, and the development of contractures. These factors are summarized in Table 4.1.

Contracture

Restricted motion can range from mild muscle shortening to irreversible contractures. *Contracture* is defined as the adaptive shortening of the muscle-tendon unit and other soft tissues that cross or surround a joint resulting in significant resistance to passive or active stretch and limitation of ROM, which may compromise functional abilities.[11,35,53,87,113]

There is no clear delineation of how much limitation of motion from loss of soft tissue extensibility must exist to designate the limitation of motion as a contracture. In one reference,[87]

TABLE 4.1 Comparison of Terminology of Two Disablement Models

Contributing Factors	Examples
Prolonged immobilization	
Extrinsic	Fractures, osteotomy, soft tissue trauma or repair
Casts and splints	
Skeletal traction	
Intrinsic	
Pain	Microtrauma or macrotrauma; degenerative diseases
Joint inflammation and effusion	Joint diseases or trauma
Muscle, tendon, or fascial disorders	Myositis, tendonitis, fasciitis
Skin disorders	Burns, skin grafts, scleroderma
Bony block	Osteophytes, ankylosis, surgical fusion
Vascular disorders	Peripheral lymphedema
Sedentary lifestyle and habitual faulty or asymmetrical postures	Confinement to bed or a wheelchair; prolonged positioning associated with occupation or work environment
Paralysis, tonal abnormalities, and muscle imbalances	Neuromuscular disorders and diseases: CNS or PNS dysfunction (spasticity, rigidity, flaccidity, weakness, muscle guarding, spasm)
Postural malalignment: congenital or acquired	Scoliosis, kyphosis

contracture is defined as an almost complete loss of motion, whereas the term *shortness* is used to denote partial loss of motion. The same resource discourages the use of the term *tightness* to describe restricted motion due to adaptive shortening of soft tissue despite its common usage in the clinical and fitness settings to describe mild muscle shortening. However, another resource[75] uses the term *muscle tightness* to denote adaptive shortening of the contractile and noncontractile elements of muscle.

Designation of Contractures by Location

Contractures are described by identifying the action of the shortened muscle. If a patient has shortened elbow flexors and cannot fully extend the elbow, he or she is said to have an elbow flexion contracture. When a patient cannot fully abduct the leg because of shortened adductors of the hip, he or she is said to have an adduction contracture of the hip.

Contracture Versus Contraction

The terms contracture and contraction (the process of tension developing in a muscle during shortening or lengthening) are not synonymous and should not be used interchangeably.

Types of Contracture

One way to clarify what is meant by the term *contracture* is to describe contractures by the pathological changes in the different types of soft tissues involved.[34]

Myostatic contracture. In a myostatic (myogenic) contracture, although the musculotendinous unit has adaptively shortened and there is a significant loss of ROM, there is no specific muscle pathology present.[34] From a morphological perspective, although there may be a reduction in the number of sarcomere units in series, there is no decrease in individual sarcomere length. Myostatic contractures can be resolved in a relatively short time with stretching exercises.[34,53]

Pseudomyostatic contracture. Impaired mobility and limited ROM may also be the result of hypertonicity (i.e., spasticity or rigidity) associated with a central nervous system lesion, such as a cerebrovascular accident, a spinal cord injury, or traumatic brain injury.[34,53] Muscle spasm or guarding and pain may also cause a pseudomyostatic contracture. In both situations, the involved muscles appear to be in a constant state of contraction, giving rise to excessive resistance to passive stretch. Hence, the term pseudomyostatic contracture or apparent contracture is used. If neuromuscular inhibition procedures to reduce muscle tension temporarily are applied, full, passive elongation of the apparently shortened muscle is then possible.

Arthrogenic and periarticular contracture. An arthrogenic contracture is the result of intra-articular pathology. These changes may include adhesions, synovial proliferation, joint effusion, irregularities in articular cartilage, or osteophyte formation.[53] A periarticular contracture develops when connective tissues that cross or attach to a joint or the joint capsule lose mobility, thus restricting normal arthrokinematic motion.

Fibrotic contracture and irreversible contracture. Fibrous changes in the connective tissue of muscle and periarticular structures can cause adherence of these tissues and subsequent development of a fibrotic contracture. Although it is possible to stretch a fibrotic contracture and eventually increase ROM, it is often difficult to re-establish optimal tissue length.[35]

Permanent loss of extensibility of soft tissues that cannot be reversed by nonsurgical intervention may occur when normal muscle tissue and organized connective tissue are replaced with a large amount of relatively nonextensible, fibrotic adhesions and scar tissue[35] or even heterotopic bone.

These changes can occur after long periods of immobilization of tissues in a shortened position or after tissue trauma and the subsequent inflammatory response. The longer a fibrotic contracture exists or the greater the replacement of normal muscle and connective tissue with nonextensible adhesions and scar tissue or bone, the more difficult it becomes to regain optimal mobility of soft tissues and the more likely it is that the contracture will become irreversible.[35,69,155]

Selective Stretching

Selective stretching is a process whereby the overall function of a patient may be improved by applying stretching techniques selectively to some muscles and joints but allowing limitation of motion to develop in other muscles or joints. When determining which muscles to stretch and which to allow to become slightly shortened, the therapist must always keep in mind the functional needs of the patient and the importance of maintaining a balance between mobility and stability for maximum functional performance.

The decision to allow restrictions to develop in selected muscle-tendon units and joints typically is made in patients with permanent paralysis. For example:

- In a patient with spinal cord injury, stability of the trunk is necessary for independence in sitting. With thoracic and cervical lesions, the patient does not have active control of the back extensors. If the hamstrings are routinely stretched to improve or maintain their extensibility and moderate hypomobility is allowed to develop in the extensors of the low back, this enables a patient to lean into the slightly shortened structures and have some degree of trunk stability for long-term sitting. However, the patient must still have enough flexibility for independence in dressing and transfers. Too much limitation of motion in the low back can decrease function.
- Allowing slight hypomobility to develop in the long flexors of the fingers while maintaining mobility of the wrist enables the patient with spinal cord injury, who lacks innervation of the intrinsic finger muscles, to regain the ability to grasp by using a tenodesis action.

Overstretching and Hypermobility

Overstretching is a stretch well beyond the normal length of muscle and ROM of a joint and the surrounding soft tissues,[87] resulting in *hypermobility* (excessive mobility).

- Creating selective hypermobility by overstretching may be necessary for certain healthy individuals with normal strength and stability, who participate in sports that require extensive flexibility.
- Overstretching becomes detrimental and creates joint *instability* when the supporting structures of a joint and the strength of the muscles around a joint are insufficient and cannot hold a joint in a stable, functional position during activities. Instability of a joint often causes pain and may predispose a person to musculoskeletal injury.

Overview of Interventions to Increase Mobility of Soft Tissues

Many therapeutic interventions have been designed to improve the mobility of soft tissues and consequently, increase ROM and flexibility. Stretching and mobilization/manipulation are general terms that describe any therapeutic maneuver that increases the extensibility of restricted soft tissues.

The following are terms that describe a number of techniques designed to increase soft tissue extensibility and joint mobility, only some of which are addressed in depth in this chapter.

Stretching: Manual or Mechanical/Passive or Assisted

A sustained or intermittent external, end-range stretch force, applied with overpressure and by manual contact or a mechanical device, elongates a shortened muscle-tendon unit and periarticular connective tissues by moving a restricted joint just past the available ROM. If the patient is as relaxed as possible, it is called *passive stretching*. If the patient assists in moving the joint through a greater range, it is called *assisted stretching*.

Self-Stretching

Any stretching exercise that is carried out independently by a patient after instruction and supervision by a therapist is referred to as *self-stretching*. The terms self-stretching and flexibility exercises are often used interchangeably. However, some practitioners prefer to limit the definition of flexibility exercises to stretching exercises that are part of a general conditioning and fitness program carried out by individuals without mobility impairments. *Active stretching* is another term sometimes used to denote self-stretching procedures. However, stretching exercises that incorporate inhibition or facilitation techniques into stretching maneuvers also have been referred to as active stretching.[168]

Neuromuscular Facilitation and Inhibition Techniques

Neuromuscular facilitation and inhibition procedures are purported to relax tension in shortened muscles reflexively prior to or during muscle elongation. Because the use of inhibition or facilitation techniques to assist with muscle elongation is associated with an approach to exercise known as proprioceptive neuromuscular facilitation (PNF),[145,158] many clinicians and some authors refer to these combined inhibition/facilitation/muscle lengthening procedures by a number of terms, including PNF stretching,[31,38,138] active inhibition,[75] active stretching,[168] or facilitated stretching.[125] Stretching procedures based on principles of PNF are discussed in a later section of this chapter.

Muscle Energy Techniques

Muscle energy techniques are manipulative procedures that have evolved out of osteopathic medicine and are designed to lengthen muscle and fascia and to mobilize joints.[23,28,167] The procedures employ voluntary muscle contractions by the patient in a precisely controlled direction and intensity

against a counterforce applied by the practitioner. Because principles of neuromuscular inhibition are incorporated into this approach, another term used to describe these techniques is *postisometric relaxation.*

Joint Mobilization/Manipulation

Joint manipulative techniques are skilled manual therapy interventions specifically applied to joint structures to modulate pain and treat joint impairments that limit ROM.[70,83] Principles of use and basic techniques for the extremity joints are described and illustrated in detail in Chapter 5. Mobilization with movement techniques for the extremities are described and illustrated throughout the regional chapters (see Chapters 17 to 22). Techniques for the ribs, sacrum, and temporomandibular joints are presented in Chapter 15, and spinal techniques are in Chapter 16.

Soft Tissue Mobilization/Manipulation

Soft tissue manipulative techniques are designed to improve muscle extensibility and involve the application of specific and progressive manual forces (e.g., by means of sustained manual pressure or slow, deep stroking) to effect change in the myofascial structures that can bind soft tissues and impair mobility. Techniques, including friction massage,[75,147] myofascial release,[22,68,100,147] acupressure,[75,147,157] and trigger point therapy,[100,147,157] are designed to improve tissue mobility by manipulating connective tissue that binds soft tissues. Although they are useful adjuncts to manual stretching procedures, specific techniques are not described in this textbook.

Neural Tissue Mobilization (Neuromeningeal Mobilization)

After trauma or surgical procedures, adhesions or scar tissue may form around the meninges and nerve roots or at the site of injury at the plexus or peripheral nerves. Tension placed on the adhesions or scar tissue leads to pain or neurological symptoms. After tests to determine neural tissue mobility are conducted, the neural pathway is mobilized through selective procedures.[21,75] These maneuvers are described in Chapter 13.

Indications, Contraindications, and Potential Outcomes of Stretching Exercises

Indications and Contraindications for Stretching

There are situations in which stretching exercises are appropriate and safe; however, there are also instances when stretching should not be implemented. Boxes 4.1 and 4.2 list indications and contraindications for the use of stretching interventions.

BOX 4.1 Indications for Use of Stretching

- ROM is limited because soft tissues have lost their extensibility as the result of adhesions, contractures, and scar tissue formation, causing activity limitations (functional limitations) or participation restrictions (disabilities).
- Restricted motion may lead to structural deformities that are otherwise preventable.
- Muscle weakness and shortening of opposing tissue have led to limited ROM.
- May be a component of a total fitness or sport-specific conditioning program designed to prevent or reduce the risk of musculoskeletal injuries.
- May be used prior to and after vigorous exercise to potentially reduce postexercise muscle soreness.

BOX 4.2 Contraindications to Stretching

- A bony block limits joint motion.
- There was a recent fracture, and bony union is incomplete.
- There is evidence of an acute inflammatory or infectious process (heat and swelling), or soft tissue healing could be disrupted in the restricted tissues and surrounding region.
- There is sharp, acute pain with joint movement or muscle elongation.
- A hematoma or other indication of tissue trauma is observed.
- Hypermobility already exists.
- Shortened soft tissues provide necessary joint stability in lieu of normal structural stability or neuromuscular control.
- Shortened soft tissues enable a patient with paralysis or severe muscle weakness to perform specific functional skills otherwise not possible.

Potential Benefits and Outcomes of Stretching

Increased Flexibility and ROM

The primary effect and expected outcome of a program of stretching exercises is to restore or increase the extensibility of the muscle-tendon unit and, therefore, regain or achieve the flexibility and ROM required for necessary or desired functional activities. A considerable body of evidence has shown that the various types of stretching exercises, particularly static and PNF stretching procedures, improve flexibility and increase ROM. (The parameters of stretching exercises that determine effectiveness, such as intensity, duration, and frequency, necessary to improve flexibility and ROM are discussed later in this chapter.)

The underlying mechanisms for stretch-induced gains in ROM include biomechanical and neural changes in the contractile and noncontractile elements of the muscle-tendon

unit. These changes are thought to be the result of increased muscle extensibility and length or decreased muscle stiffness (passive muscle-tendon tension).[57,106,108,114,133] (These underlying effects are discussed in the next section of this chapter.) There is also speculation that increased ROM following stretching may be the result, at least in part, of a change in an individual's perception or tolerance of the sensation associated with stretching.[93,162]

General Fitness

In addition to improving flexibility and ROM, stretching exercises routinely are recommended for warm-up prior to or cool-down following strenuous physical activity. They are also considered to be an essential part of conditioning programs for general fitness, for recreational or workplace activities, and for training in preparation for competitive sports.

Other Potential Benefits

Potential benefits and outcomes traditionally attributed to stretching exercises by practitioners include the prevention or reduction of the risk of soft tissue injuries, reduced postexercise (delayed onset) muscle soreness, and enhanced physical performance.[48,72,76,81,139,144,170] However, the evidence to support these assumptions is inconclusive.

Injury prevention and reduced postexercise muscle soreness. Although decreased flexibility has been shown to be associated with a greater risk of musculotendinous injuries in the lower extremities,[169] the question of whether a program of stretching exercises can prevent or reduce the risk of injuries has not been answered conclusively. Few studies have suggested that stretching, as part of a warm-up routine immediately before vigorous physical activity, prevents or reduces the risk of injury. The vast majority of studies, analyzed in several critical reviews of the literature, have indicated that there is little, if any, link between an acute bout of stretching for warm-up prior to a strenuous event and the prevention or reduction of the likelihood of soft tissue injuries [73,128,133,150] or the severity or duration of postexercise, delayed-onset muscle soreness.[73]

Enhanced performance. Another suggested benefit and outcome frequently attributed to stretching is enhanced physical performance, such as increased muscular strength, power, or endurance or improvements in physical functioning, including walking or running speed and jumping abilities.

Consequently, it is common practice for an individual, who is participating in a fitness or sport-related training program, to perform stretching exercises prior to a strength training session. Stretching is also commonly performed just before participation in an athletic event requiring strength or power, such as sprinting or performing a vertical jump. However, neither practice is based on sound scientific evidence.

To effectively evaluate the impact of stretching on physical performance, a distinction must be made between a bout of stretching carried out just before a strenuous activity (*acute or pre-event stretching*) and a program of stretching exercises performed on a regular basis over a period of weeks (*chronic stretching*). A systematic review of the literature[132] and subsequent studies[32] indicate that acute stretching either has no effect or decreases—rather than enhances—muscle performance (strength, power, or endurance) immediately following the stretching session. Acute stretching also provides no benefit or has a negative effect on the performance of activities that require strength, such as sprinting or jumping.[57,117,132,140]

Based on a limited number of studies, performing stretching exercises as part of a comprehensive conditioning program on a regular basis over a period of weeks (*chronic stretching*) not only increases flexibility but also appears to have beneficial effects on physical performance. This approach to stretching has been found to improve strength or power[64,91,132,140,170] perhaps because of an alteration in the length-tension relationships of the stretched muscles. Participating in a stretching program on a regular basis also has been shown to improve gait economy[63,64] and enhance the performance of physical activities, such as sprinting and jumping abilities.[132,140]

Properties of Soft Tissue: Response to Immobilization and Stretch

The ability of the body to move freely—that is, without restrictions and with control during functional activities—is dependent on the passive extensibility of soft tissues as well as active neuromuscular control. Motion is necessary for the health of tissues in the body.[115] As mentioned previously, the soft tissues that can become restricted and impair mobility are muscles with their contractile and noncontractile elements and various types of connective tissue (tendons, ligaments, joint capsules, fascia, skin). For the most part, decreased extensibility of connective tissue, not the contractile elements of muscle tissue, is the primary cause of restricted ROM in both healthy individuals and patients with impaired mobility as the result of injury, disease, or surgery.

Morphological adaptations of tissues often accompany immobilization. Each type of soft tissue has unique properties that affect its response to immobilization and its ability to regain extensibility after immobilization. When stretching procedures are applied to these soft tissues, the direction, velocity, intensity (magnitude), duration, and frequency of the stretch force as well as tissue temperature, tension, and stiffness affect the responses of the various types of soft tissue and the outcome of stretching programs.

Mechanical characteristics of contractile and noncontractile soft tissue and the neurophysiological properties of contractile tissue affect tissue lengthening. Aside from these properties, there is also some thought that increased extensibility of the muscle-tendon unit following stretching is the result of a modification of the sensation of stretch,

such as the onset of end-range discomfort, perceived by an individual.[108,162]

Most of the information on the biomechanical, biochemical, and neurophysiological responses of soft tissues to immobilization and remobilization is derived from animal studies; as such, the exact physiological mechanism by which stretching procedures produce an increase in the extensibility of human tissues is still unclear. However, recent studies using ultrasound imaging on musculotendinous tissue in a noninvasive *in vivo* state in humans have provided confirmation of previous experiments on tendon adaptability to stress using isolated material.[92,105] An understanding of the properties of these tissues and their responses to immobilization and stretch is the basis for selecting and applying the safest, most effective stretching procedures in a therapeutic exercise program for patients with impaired mobility.[63,64]

When soft tissue is stretched, elastic, viscoelastic, or plastic changes occur. Both contractile and noncontractile tissues have elastic and plastic qualities; however, only noncontractile connective tissues, not the contractile elements of muscle, have viscoelastic properties.

- *Elasticity* is the ability of soft tissue to return to its prestretch resting length directly after a short-duration stretch force has been removed.[26,40,96,97,119]
- *Viscoelasticity,* or viscoelastic deformation, is a time-dependent property of soft tissue that initially resists deformation, such as a change in length, of the tissue when a stretch force is first applied. If a stretch force is sustained, viscoelasticity allows a change in the length of the tissue and then enables the tissue to return gradually to its prestretch state after the stretch force has been removed.[96,106,107,119,149,162]
- *Plasticity,* or plastic deformation, is the tendency of soft tissue to assume a new and greater length after the stretch force has been removed.[59,96,155,162]

Mechanical Properties of Contractile Tissue

Muscle is composed of both contractile and noncontractile connective tissues. The contractile elements of muscle (Fig. 4.1) give it the characteristics of contractility and irritability.

The noncontractile connective tissue in and around muscle (Fig. 4.2) has the same properties as all connective tissue, including the ability to resist deforming forces.[26,106,107] The connective tissue structures, which act as a "harness" of a muscle, are the *endomysium,* which is the innermost layer that separates individual muscle fibers and myofibrils; the *perimysium,* which encases fiber bundles; and the *epimysium,* which is the enveloping fascial sheath around the entire muscle. It is the connective tissue framework of muscle that is the primary source of a muscle's resistance to passive elongation.[26,35,119] When contractures develop, adhesions in and between collagen fibers resist and restrict movement.[35]

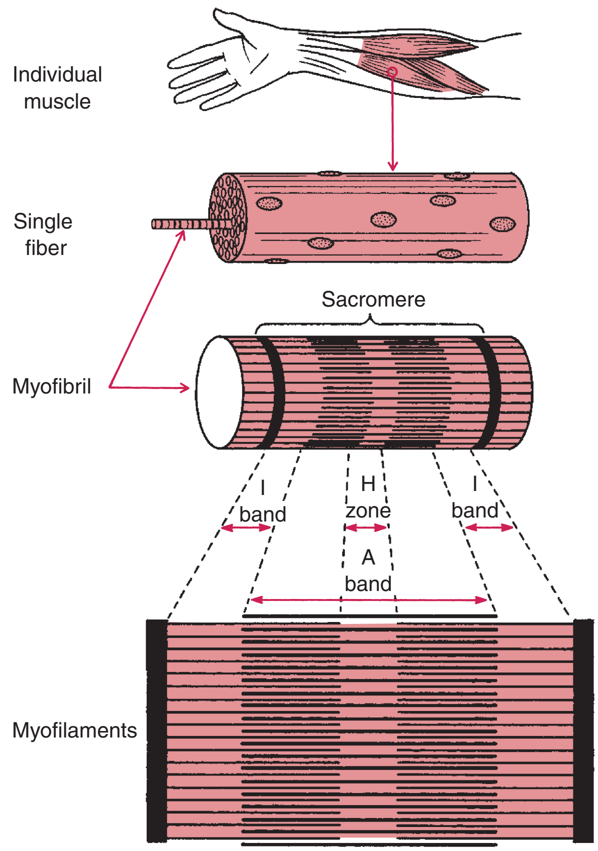

FIGURE 4.1 Structure of skeletal muscle.

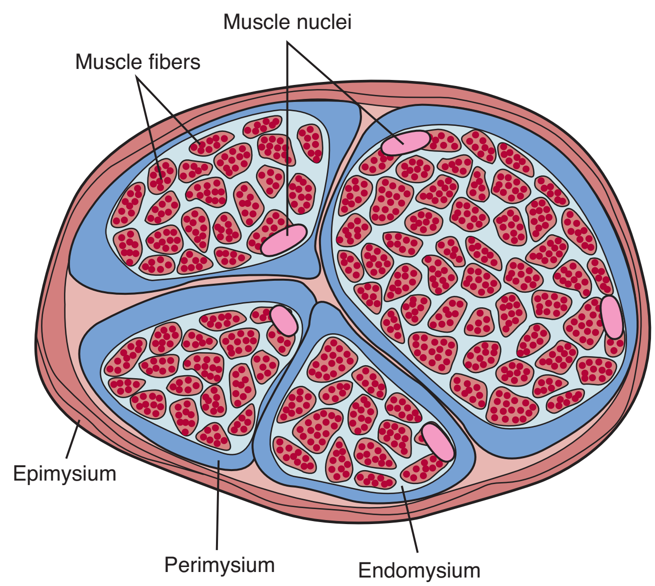

FIGURE 4.2 Muscular connective tissue. Cross-sectional view of the connective tissue in a muscle shows how the perimysium is continuous with the outer layer of epimysium. *(From Chleboun in Levangie and Norkin:* Joint Structure and Function,[26] *p 117, with permission.)*

Contractile Elements of Muscle

Individual muscles are composed of many muscle fibers that lie in parallel with one another. A single muscle fiber is made up of many myofibrils. Each myofibril is composed of even smaller structures called sarcomeres, which lie in series (end-to-end) within a myofibril. The sarcomere is the contractile unit of the myofibril and is composed of overlapping myofilaments of actin and myosin that form cross-bridges. The sarcomere gives a muscle its ability to contract and relax. When a motor unit stimulates a muscle to contract, the actin-myosin filaments slide together, and the muscle actively shortens. When a muscle relaxes, the cross-bridges slide apart slightly, and the muscle returns to its resting length (Fig. 4.3).

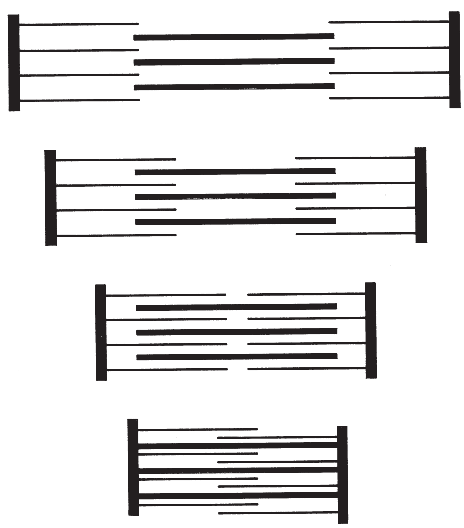

FIGURE 4.3 A model of myofilament sliding. Elongation and shortening of the sarcomere, the contractile unit of muscle.

Mechanical Response of the Contractile Unit to Stretch and Immobilization

There are a number of changes that occur over time in the anatomical structure and physiological function of the contractile units (sarcomeres) in muscle if a muscle is stretched during an exercise or if it is immobilized in either a lengthened or shortened position for an extended period of time and then remobilized. A discussion of these changes follows. Of course, the noncontractile structures in and around muscle also affect a muscle's response to stretch and immobilization.[33,96,149] Those responses and adaptations are discussed later in the chapter.

Response to Stretch

When a muscle is stretched and elongates, the stretch force is transmitted to the muscle fibers via connective tissue (endomysium and perimysium) in and around the fibers. It is hypothesized that molecular interactions link these noncontractile elements to the contractile unit of muscle, the sarcomere.[40]

During passive stretch, both longitudinal and lateral force transduction occurs.[40] When initial lengthening occurs in the series elastic (connective tissue) component, tension rises sharply. After a point, there is mechanical disruption (influenced by neural and biochemical changes) of the cross-bridges as the filaments slide apart, leading to abrupt lengthening of the sarcomeres,[40,56,96,97] sometimes referred to as *sarcomere give*.[56] When the stretch force is released, the individual sarcomeres return to their resting length [40,96,97] (see Fig. 4.3). As noted previously, the tendency of muscle to return to its resting length after short-term stretch is called elasticity. If longer lasting or more permanent (viscoelastic or plastic) length increases are to occur, the stretch force must be maintained over an extended period of time.[40,96,162]

Response to Immobilization and Remobilization

Morphological changes. If a muscle is immobilized for a prolonged period of time, the muscle is not used during functional activities, and consequently, the physical stresses placed on the muscle are substantially diminished. This results in decay of contractile protein in the immobilized muscle, as well as decreases in muscle fiber diameter, the number of myofibrils, and intramuscular capillary density, the outcome of which is muscle *atrophy* and *weakness* (decreased force-generating capacity of muscle).[12,19,65,82,85,96,115,151] As the immobilized muscle atrophies, an increase in fibrous and fatty tissue in muscle also occurs.[115]

The composition of muscle affects its response to immobilization, with atrophy occurring more quickly and more extensively in tonic (slow-twitch) postural muscle fibers than in phasic (fast-twitch) fibers.[96,97] The duration and position of immobilization also affect the extent of atrophy and loss of strength and power. The longer the duration of immobilization, the greater is the atrophy of muscle and loss of functional strength. Atrophy can begin within as little as a few days to a week.[84,85,151] Not only is there a decrease in the cross-sectional size of muscle fibers over time, an even more significant deterioration in motor unit recruitment occurs as reflected by electromyographic (EMG) activity.[96,97] Both compromise the force-producing capabilities of the muscle.

Immobilization in a shortened position. As documented in animal models, when a muscle is immobilized in a shortened position for several weeks, which is often necessary after a fracture or surgical repair of a muscle tear or tendon rupture, there is a reduction in the length of the muscle and its fibers and in the number of sarcomeres in series within myofibrils as the result of *sarcomere absorption*.[82,96,146] This absorption occurs at a faster rate than the muscle's ability to regenerate sarcomeres in an attempt to restore itself. The decrease in the overall length of the muscle fibers and their in-series sarcomeres, in turn, contributes to muscle atrophy and weakness. It has also been suggested that a muscle immobilized in a shortened position atrophies and weakens at a faster rate than if it is held in a lengthened position over time.[19]

There is a shift to the left in the length-tension curve of a shortened muscle, which decreases the muscle's capacity to produce maximum tension at its normal resting length as it contracts.[26] The increased proportion of fibrous tissue and subcutaneous fat in muscle that occurs with immobilization contributes to the decreased extensibility of the shortened muscle but may also serve to protect the weakened muscle when it stretches.[35,65]

Immobilization in a lengthened position. Sometimes a limb is immobilized in a position of maximum available length for a prolonged period of time. This occurs with some surgical procedures, such as a limb lengthening,[13] the application of a series of positional casts (serial casts),[77] or the use of a dynamic splint to stretch a long-standing contracture and increase ROM.[11,110] There is some evidence from animal studies,[146] but very limited evidence from studies involving human skeletal muscle,[13] to suggest that if a muscle is held in a lengthened position for an extended time period, it adapts by increasing the number of sarcomeres in series, sometimes referred to as *myofibrillogenesis.*[40] It is theorized that sarcomere number addition occurs to maintain the greatest functional overlap of actin and myosin filaments in the muscle[96] and may lead to a relatively permanent (plastic) form of muscle lengthening if the newly gained length is used on a regular basis in functional activities.

The minimum time frame necessary for a stretched muscle (fiber) to become a longer muscle (fiber) by adding sarcomeres in series is not known. In animal studies that have reported increased muscle length as the result of sarcomere number addition, the stretched muscle was continuously immobilized in a lengthened position for several weeks.96 There is often speculation in the clinical setting, rather than direct evidence, that this same process occurs and contributes to gains in muscle length (indirectly identified by increases in joint ROM) following the use of serial casts,77 dynamic splints,110 and perhaps as the result of stretching exercises.40 However, direct evidence of sarcomere adaptation in human skeletal muscle recently was reported following long-term, continuous limb distraction to achieve lengthening of a patient's femur.13

The adaptation of the contractile units of muscle (an increase or decrease in the number of sarcomeres) to prolonged positioning in either lengthened or shortened positions is transient, lasting only 3 to 5 weeks if the muscle resumes its pre-immobilization use and degree of lengthening for functional activities.85,96 In clinical situations, this underscores the need for patients to use full-range motions during a variety of functional activities to maintain the stretch-induced gains in muscle extensibility and joint ROM.

Neurophysiological Properties of Contractile Tissue

The neurophysiological properties of the muscle-tendon unit also may influence a muscle's response to stretch and the effectiveness of stretching interventions to elongate muscle. In particular, two sensory organs of muscle-tendon units, the *muscle spindle* and the *Golgi tendon organ*, are mechanoreceptors that convey information to the central nervous system about what is occurring in a muscle-tendon unit and that affect a muscle's response to stretch.

Muscle Spindle

The muscle spindle is the major sensory organ of muscle and is sensitive to quick and sustained (tonic) stretch (Fig. 4.4). The main function of muscle spindles is to receive and convey information about changes in the length of a muscle and the velocity of the length changes.

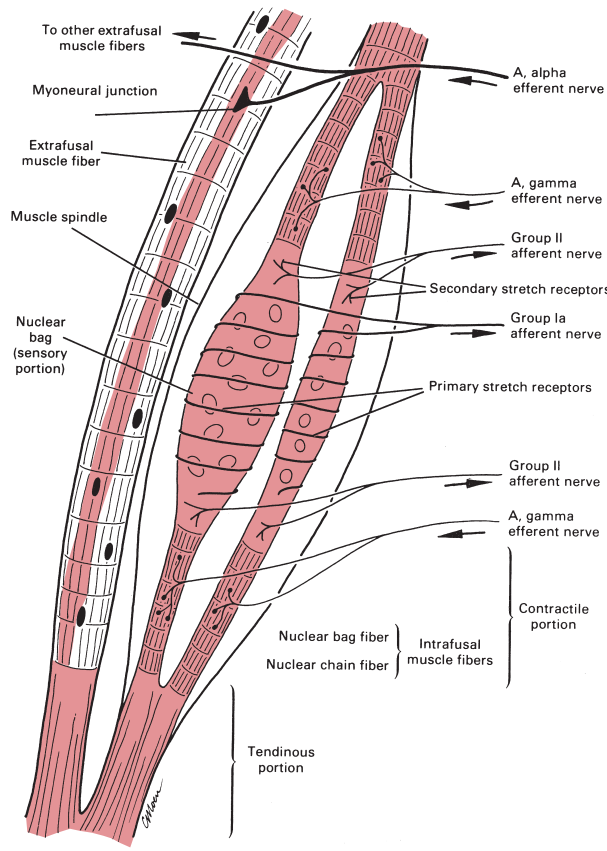

FIGURE 4.4 Muscle spindle. Diagram shows intrafusal and extrafusal muscle fibers. The muscle spindle acts as a stretch receptor. *(From Lemkuhl, LD, Smith, LK:* Brunnstrom's Clinical Kinesiology, *ed. 4. Philadelphia, FA Davis, 1983, p 97, with permission.)*

Muscle spindles are small, encapsulated receptors composed of afferent sensory fiber endings, efferent motor fiber endings, and specialized muscle fibers called *intrafusal fibers*. Intrafusal muscle fibers are bundled together and lie between and parallel to extrafusal muscle fibers that make up the main body of a skeletal muscle.[65,78,101,127] Because intrafusal muscle fibers connect at their ends to extrafusal muscle fibers, when a muscle is stretched, intrafusal fibers are also stretched. Only the ends (polar regions), not the central portion (equatorial region), of an intrafusal fiber are contractile. Consequently,

when an intrafusal muscle fiber is stimulated and contracts, it lengthens the central portion. Small-diameter motor neurons, known as *gamma* motor neurons, innervate the contractile polar regions of intrafusal muscle fibers and adjust the sensitivity of muscle spindles. Large-diameter *alpha* motor neurons innervate extrafusal fibers.

There are two general types of intrafusal fiber: *nuclear bag fibers* and *nuclear chain fibers*, so named because of the arrangement of their nuclei in the central portions of the fibers. Primary (type Ia fiber) afferent endings, which arise from nuclear bag fibers, sense and cause muscle to respond to both quick and sustained (tonic) stretch. However, secondary (type II) afferents from the nuclear chain fibers are sensitive only to tonic stretch. Primary and secondary fibers synapse on the alpha or gamma motoneurons, which when stimulated cause excitation of their own extrafusal and intrafusal fibers, respectively. There are essentially two ways to stimulate these sensory fibers by means of stretch—one is by overall lengthening of the muscle; the other is by stimulating contraction of intrafusal fibers via the gamma efferent neural pathways.

Golgi Tendon Organ

The Golgi tendon organ (GTO) is a sensory organ located near the musculotendinous junctions of extrafusal muscle fibers. The function of a GTO is to monitor changes in tension of muscle-tendon units. These encapsulated nerve endings are woven among collagen strands of a tendon and transmit sensory information via Ib fibers. These sensory organs are sensitive to even slight changes of tension on a muscle-tendon unit as the result of passive stretch of a muscle or with active muscle contractions during normal movement.

When tension develops in a muscle, the GTO fires, inhibits alpha motoneuron activity, and decreases tension in the muscle-tendon unit being stretched.[24,65,78,127] With respect to the neuromuscular system, *inhibition* is a state of decreased neuronal activity and altered synaptic potential, which reflexively diminishes the capacity of a muscle to contract.[76,78,101]

Originally, the GTO was thought to fire and inhibit muscle activation only in the presence of high levels of muscle tension as a protective mechanism. However, the GTO has since been shown to have a low threshold for firing (fires easily), so it can continuously monitor and adjust the force of active muscle contractions during movement or the tension in muscle during passive stretch.[58,127]

Neurophysiological Response of Muscle to Stretch

When a stretch force is applied to a muscle-tendon unit either quickly or over a prolonged period of time, the primary and secondary afferents of intrafusal muscle fibers sense the length changes and activate extrafusal muscle fibers via alpha motor neurons in the spinal cord, thus activating the stretch reflex and increasing (facilitating) tension in the muscle being stretched. The increased tension causes resistance to lengthening and, in turn, is thought to compromise the effectiveness of the stretching procedure.[8,44] When the stretch reflex is activated in a muscle being lengthened, decreased activity (inhibition) in the muscle on the opposite side of the joint, referred to as *reciprocal inhibition*, also may occur.[101,158] However, this phenomenon has been documented only in studies using animal models.[24,98,138,162] To minimize activation of the stretch reflex and the subsequent increase in muscle tension and reflexive resistance to muscle lengthening during stretching procedures, a slowly applied, low-intensity, prolonged stretch is considered preferable to a quickly applied, short-duration stretch.

In contrast, the GTO, as it monitors tension in the muscle fibers being stretched, has an inhibitory impact on the level of muscle tension in the muscle-tendon unit in which it lies, particularly if the stretch force is prolonged. This effect is called *autogenic inhibition*.[65,101,127] Inhibition of the contractile components of muscle by the GTO is thought to contribute to reflexive muscle relaxation during a stretching maneuver, enabling a muscle to be elongated against less muscle tension. Consequently, if a low-intensity, slow stretch force is applied to muscle, the stretch reflex is less likely to be activated as the GTO fires and inhibits tension in the muscle, allowing the parallel elastic component (the sarcomeres) of the muscle to remain relaxed and to lengthen.

In summary, when critically analyzing studies of the mechanical and neurophysiological properties of muscle, current thinking suggests that improvement in muscle extensibility attributed to stretching procedures is more likely due to tensile stresses placed on the viscoelastic, noncontractile connective tissue in and around muscle than to inhibition (reflexive relaxation) of the contractile elements of muscle.[24,106,107,108,138,149] A discussion of the effects of stretching on noncontractile soft tissue follows.

Mechanical Properties of Noncontractile Soft Tissue

Noncontractile soft tissue permeates the entire body and is organized into various types of connective tissue to support the structures of the body. Ligaments, tendons, joint capsules, fasciae, noncontractile tissue in muscles (see Fig. 4.2), and skin have connective tissue characteristics that can lead to the development of adhesions and contractures and, thus, affect the flexibility of the tissues crossing joints. When these tissues restrict ROM and require stretching, it is important to understand how they respond to the intensity and duration of stretch forces and to recognize that the only way to increase the extensibility of connective tissue is to remodel its basic architecture.[35]

Composition of Connective Tissue

Connective tissue is composed of three types of fiber: collagen, elastin and reticulin, and nonfibrous ground substance (proteoglycans and glycoproteins).[36,69,155]

Collagen fibers. Collagen fibers are responsible for the strength and stiffness of tissue and resist tensile deformation.

Tropocollagen crystals form the building blocks of collagen microfibrils. Each additional level of composition of the fibers is arranged in an organized relationship and dimension (Fig. 4.5). There are six classes with 19 types[31] of collagen; the fibers of tendons and ligaments mostly contain type I collagen, which is highly resistant to tension.[155] As collagen fibers develop and mature, they bind together, initially with unstable hydrogen bonding, which then converts to stable covalent bonding. The stronger the bonds, the greater is the mechanical stability of the tissue. Tissue with a greater proportion of collagen provides greater stability.

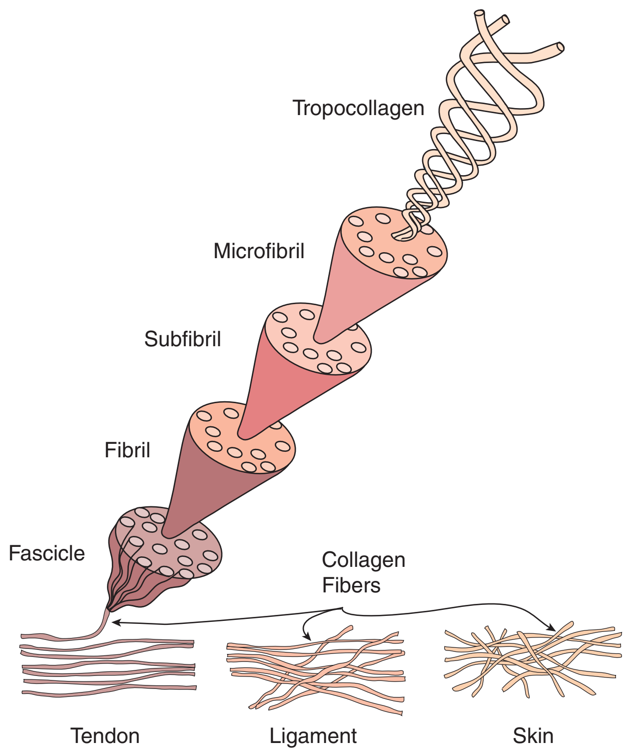

FIGURE 4.5 Composition of collagen fibers showing the aggregation of tropocollagen crystals as the building blocks of collagen. Organization of the fibers in connective tissue is related to the function of the tissue. Tissues with parallel fiber orientation, such as tendons, are able to withstand greater tensile loads than tissue, such as skin, in which the fiber orientation appears more random.

Elastin fibers. Elastin fibers provide extensibility. They show a great deal of elongation with small loads and fail abruptly without deformation at higher loads. Tissues with greater amounts of elastin have greater flexibility.

Reticulin fibers. Reticulin fibers provide tissue with bulk.

Ground substance. Ground substance is made up of proteoglycans (PGs) and glycoproteins. The PGs function to hydrate the matrix, stabilize the collagen networks, and resist compressive forces. (This is most important in cartilage and intervertebral discs.) The type and amount of PGs are proportional to the types of compressive and tensile stress that the tissue undergoes.[36] The glycoproteins provide linkage between the matrix components and between the cells and matrix opponents. In essence, the ground substance is mostly an organic gel containing water that reduces friction between fibers, transports nutrients and metabolites, and may help prevent excessive cross-linking between fibers by maintaining space between fibers.[45,155]

Mechanical Behavior of Noncontractile Tissue

The mechanical behavior of the various noncontractile tissues is determined by the proportion of collagen and elastin fibers and by the structural orientation of the fibers. The proportion of proteoglycans (PGs) also influences the mechanical properties of connective tissue. Those tissues that withstand high tensile loads are high in collagen fibers; those that withstand greater compressive loads have greater concentrations of PGs. The composition of the tissue changes when the load changes.[36]

Collagen is the structural element that absorbs most of the tensile stress. Its mechanical behavior is explained with reference to the stress-strain curve described in the following paragraphs. Collagen fibers elongate quickly under light loads (wavy fibers align and straighten). With increased loads, tension in the fibers increases, and the fibers stiffen. The fibers strongly resist the tensile force, but with continued loading, the bonds between collagen fibers begin to break. When a substantial number of bonds are broken, the fibers fail. When tensile forces are applied, the maximum elongation of collagen is less than 10%, whereas elastin may lengthen 150% and return to its original configuration. Collagen is five times as strong as elastin. The alignment of collagen fibers in various tissues reflects the tensile forces acting on that tissue (see Fig. 4.5):

- In tendons, collagen fibers are parallel and can resist the greatest tensile load. They transmit forces to the bone created by the muscle.
- In skin, collagen fibers are random and weakest in resisting tension.
- In ligaments, joint capsules, and fasciae, the collagen fibers vary between the two extremes, and they resist multidirectional forces. Ligaments that resist major joint stresses have a more parallel orientation of collagen fibers and a larger cross-sectional area.[121]

Interpreting Mechanical Behavior of Connective Tissue: The Stress-Strain Curve

The stress-strain curve illustrates the mechanical strength of structures (Fig. 4.6) and is used to interpret what is happening to connective tissue under stress loads.[36,153,155] When a tensile force is applied to a structure, it produces elongation; the stress-strain curve illustrates the strength properties, stiffness, and amount of energy the material can store before failure of the structure.

- *Stress* is force (or load) per unit area. Mechanical stress is the internal reaction or resistance to an external load.
- *Strain* is the amount of deformation or lengthening that occurs when a load (or stretch force) is applied.

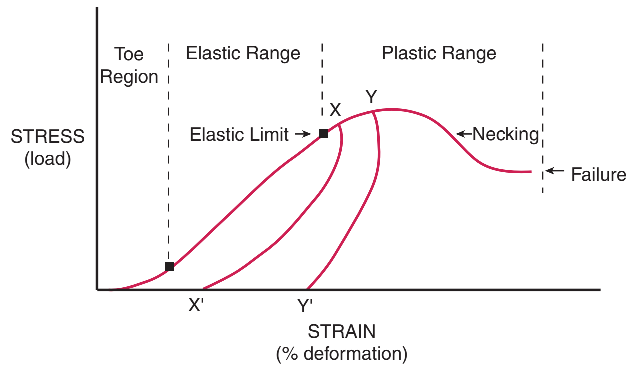

FIGURE 4.6 Stress-strain curve. When stressed, initially the wavy collagen fibers straighten (toe region). With additional stress, recoverable deformation occurs in the elastic range. Once the elastic limit is reached, sequential failure of the collagen fibers and tissue occurs in the plastic range, resulting in release of heat (hysteresis) and new length when the stress is released. The length from the stress point (X) results in a new length when released (X´); the heat released is represented by the area under the curve between these two points (hysteresis loop). (Y to Y´ represents additional length from additional stress with more heat released.) Necking is the region in which there is considerable weakening of the tissue, and less force is needed for deformation. Total failure quickly follows even under small loads.

Types of Stress

There are three kinds of stress that cause strain to structures:

- *Tension*—a force applied perpendicular to the cross-sectional area of the tissue in a direction away from the tissue. A stretching force is a tension stress.
- *Compression*—a force applied perpendicular to the cross-sectional area of the tissue in a direction toward the tissue. Muscle contraction and loading of a joint during weight bearing cause compression stresses in joints.
- *Shear*—a force applied parallel to the cross-sectional area of the tissue.

Regions of the Stress-Strain Curve

Toe region. That area of the stress-strain curve in which there is considerable deformation without the use of much force is called the toe region. This is the range in which most functional activity normally occurs. Collagen fibers at rest are wavy and are situated in a three-dimensional matrix, so some distensibility in the tissue occurs by straightening and aligning the fibers.

Elastic range/linear phase. Strain is directly proportional to the ability of tissue to resist the force. This occurs when tissue is taken to the end of its ROM, and gentle stretch is applied. With stress in this phase, the collagen fibers line up with the applied force; the bonds between fibers and between the surrounding matrix are strained; some microfailure between the collagen bonds begins; and some water may be displaced from the ground substance. There is complete recovery from this deformation, and the tissue returns to its original size and shape when the load is released if the stress is not maintained for any length of time. (See the following discussion on creep and stress-relaxation for prolonged stretch.)

Elastic limit. The point beyond which the tissue does not return to its original shape and size is the elastic limit.

Plastic range. The range beyond the elastic limit extending to the point of rupture is the plastic range. Tissue strained in this range has permanent deformation when the stress is released. In this range, there is sequential failure (microfailure) of the bonds between collagen fibrils and eventually of collagen fibers. Heat is released and absorbed in the tissue. Because collagen is crystalline, individual fibers do not stretch but, instead, rupture. In the plastic range, it is the rupturing of fibers that results in increased length and is what probably occurs during stretching procedures.

Ultimate strength. The greatest load the tissue can sustain is its ultimate strength. Once this load is reached, there is increased strain (deformation) without an increase in stress required (macrofailure). The *region of necking* is reached in which there is considerable weakening of the tissue, and it rapidly fails. The therapist must be cognizant of the tissue feel when stretching because as the tissue begins necking, if the stress is maintained, there could be complete tearing of the tissue. Experimentally, maximum tensile deformation of isolated collagen fibers prior to failure is 7% to 8%. Whole ligaments may withstand strain of 20% to 40%.[121]

Failure. Rupture of the integrity of the tissue is called failure.

Structural stiffness. The slope of the linear portion of the curve (elastic range) is known as Young's modulus or modulus of elasticity and represents the stiffness of the tissue.[36] Tissues with greater stiffness have a higher slope in the elastic region of the curve, and there is less elastic deformation (elongation) under stress. Contractures and scar tissue have greater stiffness, probably because of a greater degree of bonding between collagen fibers and their surrounding matrix. Tissues with less stiffness demonstrate greater elongation under similar loads.[36]

CLINICAL TIP

The grades of ligament injuries (strains) can be related to the stress-strain curve.

Grade I—Microfailure: rupture of a few fibers in the lower part of the plastic range.
Grade II—Macrofailure: rupture of a greater number of fibers resulting in partial tear further into the plastic range.
Grade III—Complete rupture or tissue failure.

Time and Rate Influences on Tissue Deformation

Because connective tissue has viscoelastic properties, the amount of time and the rate at which a stress (load) is applied will affect the behavior of the tissue.

Creep. When a load is applied for an extended period of time, the tissue elongates, and does not return to its original length (Fig. 4.7 A). This change in length is related to the viscosity of the tissue and is therefore time-dependent. The amount of deformation depends on the amount of force and the rate at which the force is applied. Low-magnitude loads, usually in the elastic range and applied for long periods, increase the deformation of connective tissue and allow gradual rearrangement of collagen fiber bonds (remodeling) and redistribution of water to surrounding tissues.[35,97,149,153] Increasing the temperature of the part increases the creep and therefore the distensibility of the tissue.[160,164] Complete recovery from creep may occur over time, but not as rapidly as a single strain. Patient reaction dictates the time a specific load is tolerated.

Stress-relaxation. When a force (load) is applied to stretch a tissue and the length of the tissue is kept constant, after the initial creep, there is a decrease in the force required to maintain that length, and the tension in the tissue decreases[35] (Fig. 4.7 B). This, like creep, is related to the viscoelastic qualities of the connective tissue and redistribution of the water content. Stress-relaxation is the underlying principle used in prolonged stretching procedures in which the stretch position is maintained for several hours or days. Recovery (i.e., no change) versus permanent changes in length is dependent on the amount of deformation and the length of time the deformation is maintained.[35]

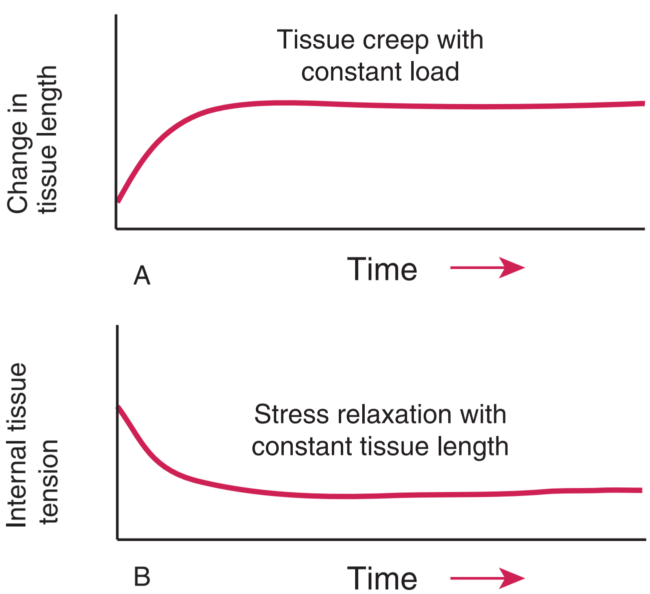

FIGURE 4.7 Tissue response to prolonged stretch forces as a result of viscoelastic properties. **(A)** Effects of creep. A constant load, applied over time, results in increased tissue length until equilibrium is reached. **(B)** Effects of stress-relaxation. A load applied with the tissue kept at a constant length results in decreased internal tension in the tissue until equilibrium is reached.

Cyclic loading and connective tissue fatigue. Repetitive loading of tissue increases heat production and may cause failure below the yield point. The greater the applied load, the fewer number of cycles needed for failure. A recent study that observed damage to rabbit medial collateral ligaments under various cyclic and static loading conditions confirmed that cyclic loading caused damage (as measured by decreased modulus) earlier than static loading.[152]

This principle can be used for stretching by applying repetitive (cyclic) loads at a submaximal level on successive days. The intensity of the load is determined by the patient's tolerance. A minimum load is required for this failure. Below the minimum load an apparently infinite number of cycles do not cause failure. This is the *endurance limit.* Examples of connective tissue fatigue from cyclic loading are stress fractures and overuse syndromes, neither of which is desired as a result of stretching. Therefore, periodically, time is allowed between bouts of cyclic stretching to allow for remodeling and healing in the new range.

Summary of Mechanical Principles for Stretching Connective Tissue

- Connective tissue deformation (stretch) occurs to different degrees at different intensities of force and at different rates of application. It requires breaking of collagen bonds and realignment of the fibers for there to be permanent elongation or increased flexibility. Failure of tissue begins as microfailure of fibrils and fibers before complete failure of the tissue occurs. Complete tissue failure can occur as a single maximal event (acute tear from a traumatic injury or manipulation that exceeds the failure point) or from repetitive submaximal stress (fatigue or stress failure from cyclic loading). Microfailure (needed for permanent lengthening) also occurs with creep, stress-relaxation, and controlled cyclic loading.
- Healing and adaptive remodeling capabilities allow the tissue to respond to repetitive and sustained loads if time is allowed between bouts. This is important for increasing both flexibility and tensile strength of the tissue. If healing and remodeling time is not allowed, a breakdown of tissue (failure) occurs as in overuse syndromes and stress fractures. Intensive stretching is usually not done every day in order to allow time for healing. If the inflammation from the microruptures is excessive, additional scar tissue, which could become more restrictive, is laid down.[35]
- It is imperative that the individual use any newly gained range to allow the remodeling of tissue and to train the muscle to control the new range, or the tissue eventually returns to its shortened length.

Changes in Collagen Affecting Stress-Strain Response

Effects of Immobilization

There is weakening of the tissue because of collagen turnover and weak bonding between the new, nonstressed fibers. There is also adhesion formation because of greater cross-linking between disorganized collagen fibers and because of decreased

effectiveness of the ground substance maintaining space and lubrication between the fibers.[45,153] The rate of return to normal tensile strength is slow. For example, after 8 weeks of immobilization, the anterior cruciate ligament in monkeys failed at 61% of maximum load; after 5 months of reconditioning, it failed at 79%; after 12 months of reconditioning, it failed at 91%.[120,122] There was also a reduction in energy absorbed and an increase in compliance (decreased stiffness) prior to failure following immobilization. Partial and near-complete recovery followed the same 5-month and 12-month pattern.[120]

Effects of Inactivity (Decrease of Normal Activity)

There is a decrease in the size and amount of collagen fibers, resulting in weakening of the tissue.[36] There is a proportional increase in the predominance of elastin fibers, resulting in increased compliance. Recovery takes about 5 months of regular cyclic loading. Physical activity has a beneficial effect on the strength of connective tissue.

Effects of Age

There is a decrease in the maximum tensile strength and the elastic modulus, and the rate of adaptation to stress is slower. There is an increased tendency for overuse syndromes, fatigue failures, and tears with stretching.[121]

Effects of Corticosteroids

There is a long-lasting deleterious effect on the mechanical properties of collagen with a decrease in tensile strength.[36] There is fibrocyte death next to the injection site with delay in reappearance up to 15 weeks.[121]

Effects of Injury

Excessive tensile loading can lead to rupture of ligaments and tendons at musculotendinous junctions.[36] Healing follows a predictable pattern (see Chapter 10), with bridging of the rupture site with newly synthesized type III collagen. This is structurally weaker than mature type I collagen. Remodeling progresses, and eventually collagen matures to type I. Remodeling usually begins about 3 weeks postinjury and continues for several months to a year, depending on the size of the connective tissue structure and magnitude of the tear.

Other Conditions Affecting Collagen

Nutritional deficiencies, hormonal imbalances, and dialysis may predispose connective tissue to injury at lower levels of stress than normal.[36]

Determinants and Types of Stretching Exercises

As with other forms of therapeutic exercise, such as strengthening exercises and endurance training, there are a number of essential elements that determine the effectiveness and outcomes of stretching interventions. The determinants (parameters) of stretching, all of which are interrelated, include *alignment* and *stabilization* of the body during stretching; the *intensity (magnitude), duration, speed, frequency,* and *mode* (type) of stretch; and the integration of neuromuscular inhibition or facilitation and functional activities into stretching programs. By manipulating the determinants of stretching interventions, which are defined in Box 4.3, a therapist has many options from which to choose when designing stretching programs that are safe and effective and meet the needs, functional goals, and capabilities of many patients. Each of these determinants is discussed in this section of the chapter.

BOX 4.3 Determinants of Stretching Interventions

- *Alignment:* Positioning a limb or the body such that the stretch force is directed to the appropriate muscle group.
- *Stabilization:* Fixation of one site of attachment of the muscle as the stretch force is applied to the other bony attachment.
- *Intensity of stretch:* Magnitude of the stretch force applied.
- *Duration of stretch:* Length of time the stretch force is applied during a stretch cycle.
- *Speed of stretch:* Speed of initial application of the stretch force.
- *Frequency of stretch*: Number of stretching sessions per day or per week.
- *Mode of stretch:* Form or manner in which the stretch force is applied (static, ballistic, cyclic); degree of patient participation (passive, assisted, active); or the source of the stretch force (manual, mechanical, self).

Many of the investigations comparing the type, intensity, duration, and frequency of stretching have been carried out with healthy, young adults as subjects. The findings and recommendations of these studies are difficult to generalize and apply to patients with long-standing contractures or other forms of tissue restriction. Therefore, many decisions, particularly those related to the type, intensity, duration, and frequency of stretching, must continue to be based on a balance of scientific evidence and sound clinical judgments by the therapist.

There are four broad categories of stretching exercises: static stretching, cyclic (intermittent) stretching, ballistic stretching, and stretching techniques based on the principles of PNF.[39,48,74,173] Each of these forms of stretching are effective in elongating muscle and increasing ROM. Each can be carried out in various manners—that is, manually or mechanically, passively or actively, and by a therapist or independently by a patient—giving rise to many terms that are used in the literature to describe stretching interventions. The stretching interventions listed in Box 4.4 are defined and discussed in this section.

Alignment and Stabilization

Just as appropriate alignment and effective stabilization are fundamental components of muscle testing and goniometry as well as ROM and strengthening exercises, they are also essential elements of effective stretching.

BOX 4.4 Types of Stretching

- Static stretching
- Cyclic/intermittent stretching
- Ballistic stretching
- Proprioceptive neuromuscular facilitation stretching procedures (PNF stretching)
- Manual stretching
- Mechanical stretching
- Self-stretching
- Passive stretching
- Active stretching

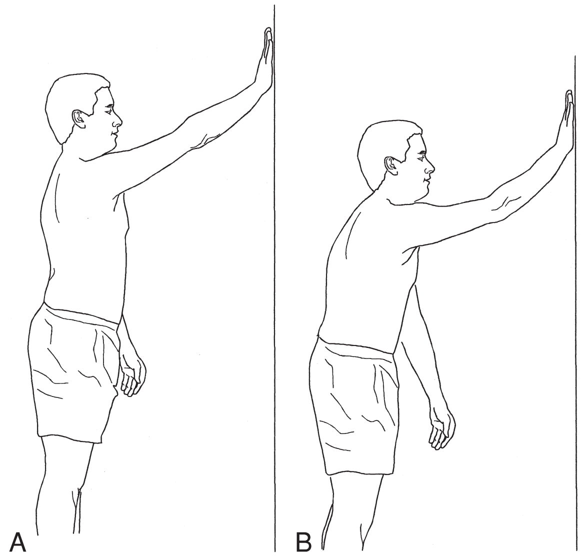

FIGURE 4.9 (A) Correct alignment when stretching to increase shoulder flexion: Note that the cervical and thoracic spine is erect. **(B)** Incorrect alignment: Note the forward head and rounded spine.

Alignment

Proper alignment or positioning of the patient and the specific muscles and joints to be stretched is necessary for patient comfort and stability during stretching. Alignment influences the amount of tension present in soft tissue and consequently affects the ROM available in joints. Alignment of the muscles and joint to be stretched as well as the alignment of the trunk and adjacent joints must all be considered. For example, to effectively stretch the rectus femoris (a muscle that crosses two joints), the lumbar spine and pelvis should be maintained in a neutral position as the knee is flexed and the hip extended. The pelvis should not tilt anteriorly nor should the low back hyperextend; the hip should not abduct or remain flexed (Fig. 4.8 A and B). When a patient is self-stretching to increase shoulder flexion, the trunk should be erect, not slumped (Fig. 4.9 A and B).

NOTE: Throughout this and later chapters, recommendations for appropriate alignment and positioning during stretching procedures are identified. If it is not possible for a patient to be placed in or assume the recommended postures because of discomfort, restrictions of motion of adjacent joints, inadequate neuromuscular control, or insufficient cardiopulmonary capacity, the therapist must critically analyze the situation to determine an alternative position.

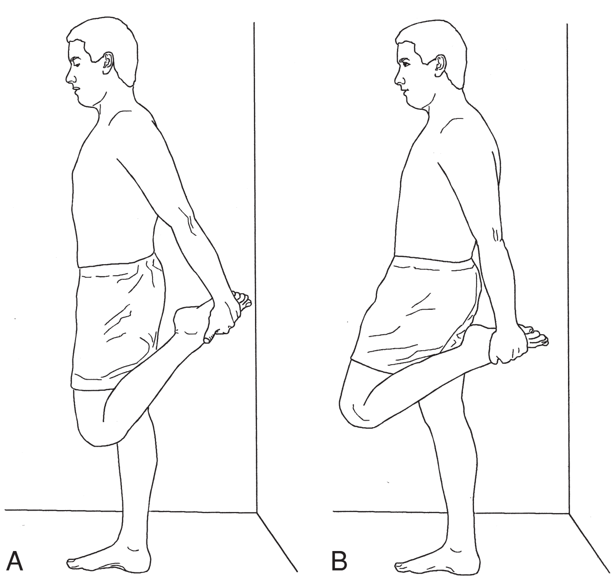

FIGURE 4.8 (A) Correct alignment when stretching the rectus femoris: The lumbar spine, pelvis, and hip are held in a neutral position as the knee is flexed. **(B)** Incorrect position of the hip in flexion. In addition, avoid anterior pelvic tilt, hyperextension of the lumbar spine, and abduction of the hip.

Stabilization

To achieve an effective stretch of a specific muscle or muscle group and associated periarticular structures, it is imperative to stabilize (fixate) either the proximal or distal attachment site of the muscle-tendon unit being elongated. Either site may be stabilized, but for manual stretching, it is common for a therapist to stabilize the proximal attachment and move the distal segment, as shown in Figure 4.10 A.

For self-stretching procedures, a stationary object, such as a chair or a doorframe, or active muscle contractions by the patient may provide stabilization of one segment as the other segment moves. During self-stretching, it is often the distal attachment that is stabilized as the proximal segment moves (Fig. 4.10 B).

Stabilization of multiple segments of a patient's body also helps maintain the proper alignment necessary for an effective stretch. For example, when stretching the iliopsoas, the pelvis and lumbar spine must maintain a neutral position as the hip is extended to avoid stress to the low back region. Sources of stabilization include manual contacts, body weight, or a firm surface, such as a table, wall, or floor.

Intensity of Stretch

The intensity (magnitude) of a stretch force is determined by the load placed on soft tissue to elongate it. There is general agreement among clinicians and researchers that

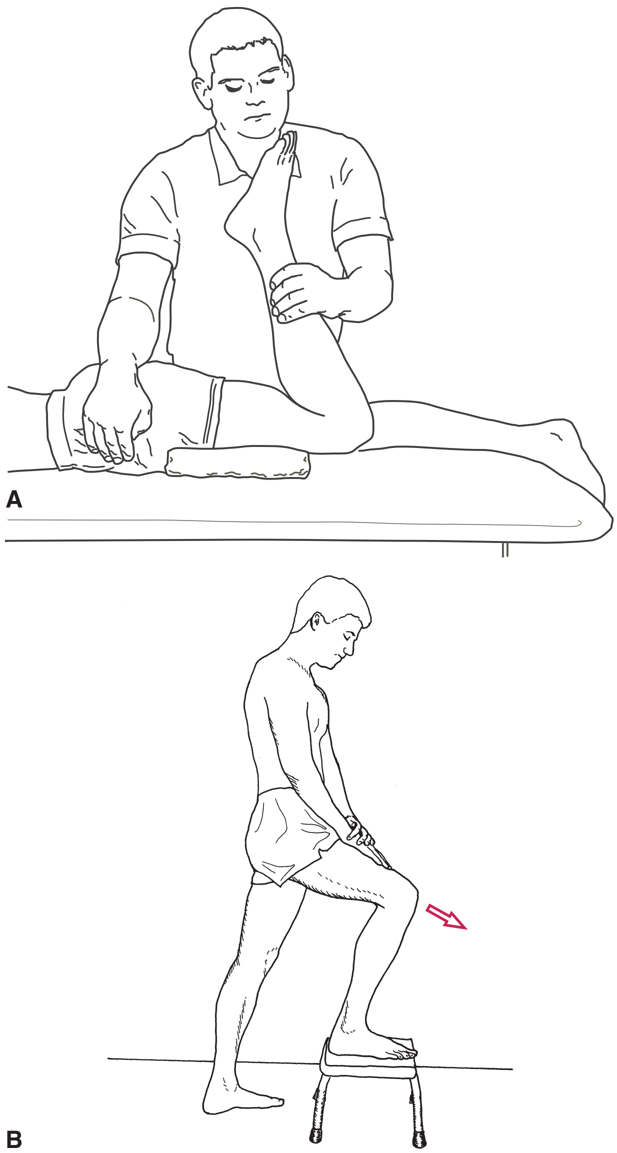

FIGURE 4.10 **(A)** The proximal attachment (femur and pelvis) of the muscle being stretched (the quadriceps) is stabilized as the distal segment is moved to increase knee flexion. **(B)** During this self-stretch of the quadriceps, the distal segment (tibia) is stabilized through the foot as the patient moves the proximal segment (femur) by lunging forward.

stretching should be applied at a *low-intensity* by means of a *low-load.*[1,11,13,30,48,74,99,103] Low-intensity stretching in comparison to high-intensity stretching makes the stretching maneuver more comfortable for the patient and minimizes voluntary or involuntary muscle guarding, so a patient can either remain relaxed or assist with the stretching maneuver.

Low-intensity stretching (coupled with a long-duration of stretch) results in optimal rates of improvement in ROM without exposing tissues, possibly weakened by immobilization, to excessive loads and potential injury.[99,103] Low-intensity stretching has also been shown to elongate dense connective tissue, a significant component of chronic contractures, more effectively and with less soft tissue damage and postexercise soreness than a high-intensity stretch.[3]

Duration of Stretch

One of the most important decisions a therapist must make when selecting and implementing a stretching intervention (stretching exercises or use of a mechanical stretching device) is to determine the duration of stretch that is expected to be safe, effective, practical, and efficient for each situation.

The duration of stretch refers to the period of time a stretch force is applied and shortened tissues are held in a lengthened position. Duration most often refers to how long a *single cycle* of stretch is applied. If more than one repetition of stretch (*stretch cycle*) is carried out during a treatment session (which is most often the case), the cumulative time of all the stretch cycles reflects the total duration of stretch, also referred to as the *total elongation time*.

In general, the shorter the duration of a single stretch cycle, the greater the number of repetitions applied during a stretching session. Many combinations have been studied.

FOCUS ON EVIDENCE

In a study by Cipriani and associates,[27] two repetitions of 30-second hamstring stretches were found to be equally effective as six repetitions of 10-second stretches. However, Roberts and Wilson[130] found that over the course of a 5-week period and equal total duration times, three 15-second hamstring stretches each day yielded significantly greater stretch-induced gains in ROM than nine daily 5-second stretches.

Despite many studies over several decades, there continues to be a lack of agreement on the "ideal" combination of the duration of a single stretch cycle and the number of repetitions of stretch that should be applied in a daily stretching program to achieve the greatest and most sustained stretch-induced gains in ROM or reduction of muscle stiffness. The duration of stretch must be put in context with other stretching parameters, including intensity, frequency, and mode of stretch. Key findings from a number of studies are summarized in Box 4.5.

Several descriptors are used to differentiate between a long-duration versus a short-duration stretch. Terms such as *static, sustained, maintained,* and *prolonged* are all used to describe a long-duration stretch, whereas terms such as *cyclic, intermittent,* or *ballistic* are used to characterize a short-duration stretch. There is no specific time period assigned to any of these descriptors, nor is there a time frame that distinguishes a long-duration from a short-duration stretch.

Static Stretching

Static stretching* is a commonly used method of stretching in which soft tissues are elongated just past the point of tissue resistance and then held in the lengthened position with a

*1,6,7,8,14,15,27,39,43,44,54,60,63,88,93,98,104,116,118,130,135,144,161,171

BOX 4.5 Intensity, Duration, Frequency, and Mode of Stretch—Evidence-Based Interrelationships and Impact on Stretching Outcomes

- There is an inverse relationship between intensity and duration as well as between intensity and frequency of stretch.
  - The lower the intensity of stretch, the longer the time the patient will tolerate stretching and the soft tissues can be held in a lengthened position.
  - The higher the intensity, the less frequently the stretching intervention can be applied to allow time for tissue healing and resolution of residual muscle soreness.
- A low-load (low-intensity), long-duration stretch is considered the safest form of stretch and yields the most significant, elastic deformation and long-term, plastic changes in soft tissues.
- Manual stretching and self-stretching in hypomobile but healthy subjects[6-8,14,27,54] and prolonged mechanical stretching in patients with chronic contractures[16,77,80,99,111] yield significant stretch-induced gains in ROM.
- In the well elderly, stretch cycles of 15, 30, and 60 seconds applied to the hamstrings for four repetitions have all been shown to produce significant gains in ROM with the greatest and longest-lasting improvements occurring with the use of repeated 60-second stretch cycles.[54]
- In healthy young and/or middle-age adults:
  - Stretch durations of 15, 30, 45, or 60 seconds or 2 minutes to lower extremity musculature produced significant gains in ROM.[6,7,27,44,104,166]
  - Stretch cycles of 30- and 60-second durations applied to the hamstrings for one repetition daily are both more effective for increasing ROM than one repetition daily of a 15-second stretch cycle but are equally effective when compared to each other.[6]
  - Two repetitions daily of a 30-second static stretch of the hamstrings yield significant gains in hamstring flexibility similar to those seen with six repetitions of 10-second static stretches daily.[27]
  - Static stretches of the hip adductors for 15 seconds or 2 minutes produce equal improvements in ROM.[104]
  - There seems to be no additional benefit to holding each stretch cycle beyond 60 seconds.[7,89]
  - Three cycles of 30-second and 1-minute stretches are no more effective for improving ROM than one cycle of each duration of stretch.[7]
- Longer total durations of passive stretch yield longer-lasting decreases in muscle-tendon stiffness than short-duration stretches.[57,106,133]
  - A 2-minute passive stretch yields only a transient decrease in stiffness of the gastrocnemius muscle of healthy, young adults; whereas 4-minute and 8-minute stretches reduce stiffness for up to 20 minutes after stretching.[133]
- When the total duration of stretch (total elongation time) is equal, cyclic stretching is equally effective and possibly more comfortable than static stretching.[143]
- For patients with chronic, fibrotic contractures:
  - Common durations of manual stretching or self-stretching (several repetitions of 15-second or 30-second stretches) may not be effective.[99,116]
  - Use of prolonged static stretch with splints or casts is more effective.[16,80,99,111]
- Frequency of stretching needs to occur a minimum of two times per week[63] for healthy hypomobile individuals, but more frequent stretching is necessary for patients with soft tissue pathology to achieve gains in ROM.
- Although stretch-induced gains in ROM often persist for several weeks to a month in healthy adults after cessation of a stretching program, permanent improvement in mobility can be achieved only by use of the newly gained ROM in functional activities and/or with a maintenance stretching program.[166]

sustained stretch force over a period of time. Other terms used interchangeably are sustained, maintained, or prolonged stretching. The duration of static stretch is predetermined prior to stretching or is based on the patient's tolerance and response during the stretching procedure.

In research studies, the term "static stretching" has been linked to durations of a single stretch cycle ranging from as few as 5 seconds to 5 minutes per repetition when either a manual stretch or self-stretching procedure is employed.[†] If a mechanical device provides the static stretch, the time frame can range from almost an hour to several days or weeks.[17,77,80,99,103,110] (See additional information on mechanical stretching later in this section.)

FOCUS ON EVIDENCE

In a systematic review of the literature (28 studies) on hamstring stretching,[39] a 30-second manual or self-stretching procedure performed for one or more repetitions was the most frequently used duration per repetition of stretch in static stretching programs. A 30-second stretch per repetition also has been identified as the median duration of stretch in a review of the literature of studies on calf muscle stretching.[171]

Static stretching is well accepted as an effective form of stretching to increase flexibility and ROM[1,39,74,75,93,118,133,162] and has been considered a safer form of stretching than ballistic stretching for decades.[43] Early research established that tension created in muscle during static stretching is approximately half that created during ballistic stretching.[159] This is consistent with our current understanding of the viscoelastic properties of connective tissue, which lies in and around muscles, as well as the neurophysiological properties of the contractile elements of muscle.

As discussed in the previous section of this chapter, noncontractile soft tissues are known to yield to a low-intensity, continuously applied stretch force, as used in static stretching.

[†]6,7,8,13,14,15,27,54,93,99,118,130,135,161,171

Furthermore, a low-intensity, slowly applied, continuous, end-range static stretch does not appear to cause significant neuromuscular activation (evidence of increased EMG activity) of the stretched muscle.[24,108] However, the assertion that static stretching contributes to neuromuscular relaxation (inhibition) of the stretched muscle, as the result of activation of the GTO, is not supported by experimental evidence in human research studies.[24,98,138]

Static Progressive Stretching

Static progressive stretching is a term that characterizes how static stretching is applied for maximum effectiveness. The shortened soft tissues are held in a comfortably lengthened position until a degree of relaxation is felt by the patient or therapist. Then the shortened tissues are incrementally lengthened even further and again held in the new end-range position for an additional duration of time.[17,80] This approach involves continuous displacement of a limb by varying the stretch force (stretch load) to capitalize on the stress-relaxation properties of soft tissue[111] (see Fig. 4.7 B).

Most studies that have explored the merits of static *progressive* stretching have examined the effectiveness of a dynamic orthosis (see Fig. 4.13), which allows the patient to control the degree of displacement of the limb.[17,80] Manual stretching and self-stretching procedures are also routinely applied in this manner.

Cyclic (Intermittent) Stretching

A relatively short-duration stretch force that is repeatedly but gradually applied, released, and then reapplied is described as a cyclic (intermittent) stretch.[14,52,112,143] Cyclic stretching, by its very nature, is applied for multiple repetitions (stretch cycles) during a single treatment session. With cyclic stretching, the end-range stretch force is applied at a slow velocity, in a controlled manner, and at relatively low-intensity. For these reasons, cyclic stretching is not synonymous with ballistic stretching, which is characterized by high-velocity movements.

The differentiation between cyclic stretching and static stretching based on the duration that each stretch is applied is not clearly defined in the literature. According to some authors, in cyclic stretching, each cycle of stretch is held between 5 and 10 seconds.[52,143] However, investigators in other studies refer to stretching that involves 5- and 10-second stretch cycles as static stretching.[27,130] There is also no consensus on the optimal number of repetitions of cyclic stretching during a treatment session. Rather, this determination is often based on the patient's response to stretching.

Based on clinical experience, some therapists hold the opinion that appropriately applied, end-range cyclic stretching is as effective but more comfortable for a patient than a static stretch of comparable intensity, particularly if the static stretch is applied continuously for more than 30 seconds. There is some evidence to support this opinion. Although there have been few studies on cyclic or intermittent stretching (aside from those on ballistic stretching), cyclic loading has been shown to increase flexibility as effectively or more effectively than static stretching.[112,143]

FOCUS ON EVIDENCE

In a study of nonimpaired young adults, 60 seconds of cyclic stretching of calf muscles caused tissues to yield at slightly lower loads than one 60-second, two 30-second, or four 15-second static stretches, possibly due to decreased muscle stiffness.[112] In another study that compared cyclic and a prolonged static stretch,[143] the authors speculated that heat production might occur because of the movement inherent in cyclic stretching and cause soft tissues to yield more readily to stretch. The authors of the latter study also concluded that cyclic stretching was more comfortable than a prolonged static stretch.

Speed of Stretch

Importance of a Slowly Applied Stretch

To minimize muscle activation during stretching and reduce the risk of injury to tissues and poststretch muscle soreness, the speed of stretch should be slow.[60,63,135] The stretch force should be applied and released gradually. A slowly applied stretch is less likely to increase tensile stresses on connective tissues [98,106,107] or to activate the stretch reflex. Remember, the Ia fibers of the muscle spindle are sensitive to the velocity of muscle lengthening. A slow rate stretch also affects the viscoelastic properties of connective tissue, making them more compliant. In addition, a stretch force applied at a low-velocity is easier for the therapist or patient to control and is, therefore, safer than a high-velocity stretch.

Ballistic Stretching

A rapid, forceful intermittent stretch—that is, a high-speed and high-intensity stretch—is commonly called ballistic stretching.[1,7,8,48,135,173] It is characterized by the use of quick, bouncing movements that create momentum to carry the body segment through the ROM to stretch shortened structures. Although both static stretching and ballistic stretching have been shown to improve flexibility equally, ballistic stretching is thought to cause greater trauma to stretched tissues and greater residual muscle soreness than static stretching.[163]

Consequently, although ballistic stretching has been shown to increase ROM safely in young, healthy subjects participating in a conditioning program,[71] it is, for the most part, not recommended for elderly or sedentary individuals or patients with musculoskeletal pathology or chronic contractures. The rationale for this recommendation is[35]:

- Tissues, weakened by immobilization or disuse, are easily injured.
- Dense connective tissue found in chronic contractures does not yield easily with high-intensity, short-duration stretch; rather, it becomes more brittle and tears more readily.

High-Velocity Stretching in Conditioning Programs and Advanced-Phase Rehabilitation

Although controversial, there are situations in which high-velocity stretching is appropriate for carefully selected individuals. For example, a highly trained athlete involved in a sport, such as gymnastics, that requires significant dynamic flexibility may need to incorporate high-velocity stretching in a conditioning program. Also, a young, active patient in the final phase of rehabilitation, who wishes to return to high-demand recreational or sport activities after a musculoskeletal injury, may need to perform carefully progressed, high-velocity stretching activities prior to beginning plyometric training or simulated, sport-specific exercises or drills.

If high-velocity stretching is employed, rapid, but *low-load* (*low-intensity*) stretches are recommended, paying close attention to effective stabilization. The following self-stretching progression is designed as a transition from static stretching to ballistic stretching to improve dynamic flexibility.[173]

- Static stretching → Slow, short end-range stretching → Slow, full-range stretching → Fast, short end-range stretching → Fast, full-range stretching.
- The stretch force is initiated by having the individual actively contract the muscle group opposite the muscle and connective tissues to be stretched.

Frequency of Stretch

Frequency of stretching refers to the number of bouts (sessions) per day or per week a patient carries out a stretching regimen. The recommended frequency of stretching is based on the underlying cause of impaired mobility, the quality and level of healing of tissues, the chronicity and severity of a contracture, as well as a patient's age, use of corticosteroids, and previous response to stretching. Because few studies have attempted to determine the optimal frequency of stretching within a day or a week, it is not possible to draw evidence-based guidelines from the literature. As with decisions on the most appropriate number of repetitions of stretch in an exercise session, most suggestions are based on opinion. Frequency on a weekly basis ranges from two to five sessions, allowing time for rest between sessions for tissue healing and to minimize postexercise soreness. Ultimately, the decision is based on the clinical discretion of the therapist and the response and needs of the patient.

A therapist must be aware of any breakdown of tissues with repetitive stretch. A fine balance between collagen tissue breakdown and repair is needed to allow an increase in soft tissue lengthening. If there is excessive frequency of loading, tissue breakdown exceeds repair. Ultimately tissue failure is a possibility. In addition, if there is progressive loss of ROM over time rather than a gain in range, continued low-grade inflammation from repetitive stress can cause excessive collagen formation and hypertrophic scarring.

Mode of Stretch

The mode of stretch refers to the form of stretch or the manner in which stretching exercises are carried out. Mode of stretch can be defined by whom or what is applying the stretch force or whether the patient is actively participating in the stretching maneuver. Categories include, but are not limited to, *manual* and *mechanical stretching* or *self-stretching* as well as *passive, assisted*, or *active stretching*. Regardless of the form of stretching selected and implemented, it is imperative that the shortened muscle remains relaxed and that the restricted connective tissues yield as easily as possible to the stretch. To accomplish this, stretching procedures should be preceded by either low-intensity active exercise or therapeutic heat to warm up the tissues that are to be lengthened.

There is no best form or type of stretching. What is important is that the therapist and patient have many modes of stretching from which to choose. Box 4.6 lists some questions a therapist needs to answer to determine which forms of stretching are most appropriate and most effective for each patient at different stages of a rehabilitation program.

Manual Stretching

Characteristics. During manual stretching, a therapist or other trained practitioner or caregiver applies an external force to move the involved body segment slightly beyond the point of tissue resistance and available ROM. The therapist manually controls the site of stabilization as well as the direction, speed, intensity, and duration of stretch. As with ROM exercises (described in Chapter 3), manual stretching can be performed passively, with assistance from the patient, or even independently by the patient.

BOX 4.6 Considerations for Selecting Methods of Stretching

- Based on the results of your examination, what tissues are involved and impairing mobility?
- Is there evidence of pain or inflammation?
- How long has the hypomobility existed?
- What is the stage of healing of restricted tissues?
- What form(s) of stretching have been implemented previously? How did the patient respond?
- Are there any underlying diseases, disorders, or deformities that might affect the choice of stretching procedures?
- Does the patient have the ability to actively participate in, assist with, or independently perform the exercises? Consider the patient's physical capabilities, age, ability to cooperate, or ability to follow and remember instructions.
- Is assistance from a therapist or caregiver necessary to execute the stretching procedures and appropriate stabilization? If so, what is the size and strength of the therapist or the caregiver who is assisting the patient with a stretching program?

Manual stretching typically employs a controlled, end-range, static, progressive stretch applied at an intensity consistent with the patient's comfort level. It is held for 15 to 60 seconds and repeated for at least several repetitions.

CLINICAL TIP

Remember—stretching and ROM exercises are not synonymous terms. Stretching takes soft tissue structures *beyond* their available length to *increase* ROM. ROM exercises stay within the limits of tissue extensibility to *maintain* the available length of tissues.

Effectiveness. Despite widespread use of manual stretching in the clinical setting, its effectiveness for increasing the extensibility of range-limiting muscle-tendon units is debatable. Although some investigators [44] have found that manual stretching increases muscle length and ROM in nonimpaired subjects, the short-duration of stretch that typically occurs with manual stretching may be why other investigators have reported a negligible effect from a manual stretching program,[66] especially in the presence of long-standing contractures associated with tissue pathology.[99]

Application. The following are points to consider about the use of manual stretching.

- Manual stretching may be most appropriate in the early stages of a stretching program when a therapist wants to determine how a patient responds to varying intensities or durations of stretch and when optimal stabilization is most critical.
- Manual stretching performed *passively* is an appropriate choice for a therapist or caregiver if a patient cannot perform self-stretching owing to a lack of neuromuscular control of the body segment to be stretched.
- If a patient has control of the body segment to be stretched, it is often helpful to ask the patient to assist the therapist with the manual stretching maneuver, particularly if the patient is apprehensive about moving and is having difficulty relaxing. For example, if the patient concentrically contracts the muscle opposite the short muscle and assists with joint movement, the range-limiting muscle tends to relax reflexively, thus decreasing muscle tension interfering with elongation. This is one of several stretching procedures based on proprioceptive neuromuscular facilitation techniques that are discussed later in this chapter.
- Using procedures and hand placements similar to those described for self-ROM exercises (see Chapter 3), a patient can also independently lengthen range-limiting muscles and periarticular tissues with manual stretching. As such, this form of stretching is usually referred to as *self-stretching* and is discussed in more detail as the next topic in this section.

NOTE: Specific guidelines for the application of manual stretching, as well as descriptions and illustrations of manual stretching techniques for the extremities (Figures 4.16 through 4.36), are presented in later sections of this chapter.

Self-Stretching

Characteristics. Self-stretching (also referred to as flexibility exercises or active stretching) is a type of stretching procedure a patient carries out independently after careful instruction and supervised practice. Self-stretching enables a patient to maintain or increase the ROM gained as the result of direct intervention by a therapist. This form of stretching is often an integral component of a home exercise program and is necessary for long-term self-management of many musculoskeletal and neuromuscular disorders.

Effectiveness. Teaching a patient to carry out self-stretching procedures *correctly* and *safely* is fundamental for preventing re-injury or future dysfunction. Proper alignment of the body or body segments is critical for effective self-stretching. Sufficient stabilization of either the proximal or distal attachment of a shortened muscle is necessary but can be difficult to achieve with self-stretching. Every effort should be made to see that restricted structures are stretched specifically and that adjacent structures are not overstretched.

Application. The guidelines for the intensity, speed, duration, and frequency of stretch that apply to manual stretching are also appropriate for self-stretching procedures. Static stretching for a 30- to 60-second duration per repetition is considered the safest type of stretching for a self-stretching program.

Self-stretching exercises can be carried out in several ways.

- Using positions for self-ROM exercises described in Chapter 3, a patient can passively move the distal segment of a restricted joint with one or both hands to elongate a shortened muscle while stabilizing the proximal segment (Fig. 4.11 A).

FIGURE 4.11 (A) When manually self-stretching the adductors and internal rotators of the hip, the patient moves the distal segment (femur) while stabilizing the proximal segment (pelvis) with body weight.

- If the distal attachment of a shortened muscle is fixed (stabilized) on a support surface, body weight can be used as the source of the stretch force to elongate the shortened muscle-tendon unit (Fig. 4.11 B).

FIGURE 4.11—cont'd (B) When self-stretching the hamstrings, the distal segment (tibia) is stabilized through the foot on the surface of a chair as the patient bends forward and moves the proximal segment. The weight of the upper body is the source of the stretch force.

- Neuromuscular inhibition, using PNF stretching techniques, can be integrated into self-stretching procedures to promote relaxation in the muscle that is being elongated.
- Low-intensity active stretching (referred to by some as *dynamic ROM*[8]), using repeated, short-duration, end-range active muscle contractions of the muscle opposite the shortened muscle is another form of self-stretching exercise.[8,161,168]

Mechanical Stretching

Characteristics. Mechanical stretching devices apply a very low-intensity stretch force (low-load) over a prolonged period of time to create relatively permanent lengthening of soft tissues, presumably due to plastic deformation.

There are many ways to use equipment to stretch shortened tissues and increase ROM. The equipment can be as simple as a cuff weight or weight-pulley system or as sophisticated as some adjustable orthotic devices or automated stretching machines.[11,17,80,95,99,103,110,143] These mechanical stretching devices provide either a constant load with variable displacement or constant displacement with variable loads.

Effectiveness. Studies[17,80] about the efficacy of the two categories of mechanical loading devices base their effectiveness on the soft tissue properties of either creep or stress-relaxation, which occur within a short period of time, as well as plastic deformation, which occurs over an extended period of time.

Be cautious of studies or product information that report "permanent" lengthening as the result of use of mechanical stretching devices. The term, "permanent," may mean that length increases were maintained for as little as a few days or a week after use of a stretching device has been discontinued. Long-term follow-up may indicate that tissues have returned to their shortened state if the newly gained motion has not been used regularly in daily activities.

Application. It is often the responsibility of a therapist to recommend the type of stretching device that is most suitable and teach a patient how to safely use the equipment and monitor its use in the home setting. A therapist may also be involved in the fabrication of serial casts or splints.

Each of the following forms of mechanical stretching has been shown to be effective, particularly in reducing long-standing contractures.

- An effective stretch load applied with a cuff weight (Fig. 4.12) can be as low as a few pounds.[99]

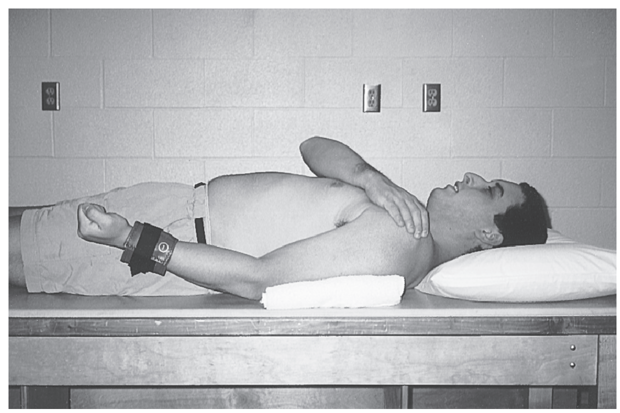

FIGURE 4.12 Low-load mechanical stretch with a cuff weight and self-stabilization of the proximal humerus to stretch the elbow flexors and increase end-range elbow extension.

- Some devices, such as the Joint Active Systems™ adjustable orthosis (Fig. 4.13), allow a patient to control and adjust the load (stretch force) during a stretching session.[17,80]
- With other devices, the load is preset prior to the application of the splint, and the load remains constant while the splint is in place.

Duration of Mechanical Stretch

Mechanical stretching involves a substantially longer overall duration of stretch than is practical with manual stretching or self-stretching exercises. The duration of mechanical stretch reported in the literature ranges from 15 to 30 minutes to as long as 8 to 10 hours at a time[17,57,80] or continuous throughout the day except for time out of the device for hygiene and exercise.[11] Serial casts are worn for days or weeks at a time before being removed and then reapplied.[77] The time

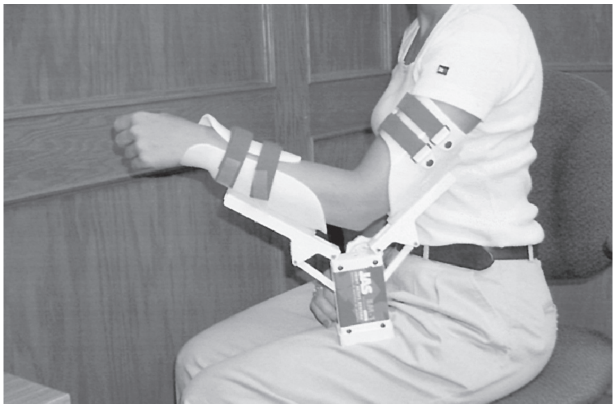

FIGURE 4.13 JAS orthosis is a patient-directed device that applies a static progressive stretch. *(Courtesy of Joint Active Systems, Effingham, IL.)*

frame is dependent on the type of device employed, the cause, severity, and chronicity of impairment, and patient tolerance. The longer durations of stretch are required for patients with chronic contractures as the result of neurological or musculoskeletal disorders rather than healthy subjects with only mild hypomobility.[17,77,80,99,103,111,116]

FOCUS ON EVIDENCE

Light and colleagues[99] studied nonambulatory, elderly nursing home residents with long-standing bilateral knee flexion contractures and compared the effects of mechanical and manual stretching. Over a 4-week period, twice-daily stretching sessions occurred 5 days per week. Low-intensity, prolonged mechanical stretching (a 5- to 12-lb stretch force applied by a weight-pulley system for 1 hour each session) was applied to one knee, and manual passive stretching was applied to the other knee by a therapist (three repetitions of 1-minute static stretches per stretching session). At the conclusion of the study, the mechanical stretching procedure was found to be considerably more effective than the manual stretching procedure for increasing knee extension. The patients also reported that the prolonged mechanical stretch was more comfortable than the manual stretching procedure, which tended to be applied at a higher intensity. The investigators recognized that the total duration of mechanical stretch (40 hours) was substantially longer over the course of the study than the total duration of manual stretch (2 hours) but believed that the manual stretching sessions were typical and practical in the clinical setting.

Proprioceptive Neuromuscular Facilitation Stretching Techniques

PNF stretching techniques,[24,74,108,123,138] sometimes referred to as *active stretching*[168] or *facilitative stretching,*[125] integrate active muscle contractions into stretching maneuvers purportedly to inhibit or facilitate muscle activation and to increase the likelihood that the muscle to be lengthened remains as relaxed as possible as it is stretched.

The traditional explanation of the underlying mechanisms of PNF stretching is that reflexive relaxation occurrs during the stretching maneuvers, as the result of autogenic or reciprocal inhibition. In turn, inhibition leads to decreased tension in muscle fibers and, therefore, decreased resistance to elongation by the contractile elements of the muscle when stretched. However, this explanation has come into question in recent years.

Current thinking suggests that gains in ROM during or following PNF stretching techniques cannot be attributed solely to autogenic or reciprocal inhibition, which involves the spinal processing of proprioceptive information. Rather, increased ROM is the result of more complex mechanisms of sensorimotor processing, most likely combined with viscoelastic adaptation of the muscle-tendon unit and changes in a patient's tolerance to the stretching maneuver.[24,108,138]

Regardless of the ongoing controversy about why PNF stretching techniques are effective, the results of numerous studies have demonstrated that the various PNF stretching techniques increase flexibility and ROM.[8,38,52,123,135,168,170] However, the degree of neuromuscular relaxation associated with the PNF stretching maneuvers investigated was not determined in these studies. There is also evidence from some studies[108,135] that PNF stretching yields greater gains in ROM than static stretching, but there is no consensus on whether one PNF technique is significantly superior to another.

Types of PNF Stretching VIDEO 4.1

There are several types of PNF stretching procedures, all of which have been shown to improve ROM. They include:

- Hold-relax (HR) or contract-relax (CR)
- Agonist contraction (AC)
- Hold-relax with agonist contraction (HR-AC).

With classic PNF, these techniques are performed with combined muscle groups acting in diagonal patterns[125,126,158] but have been modified in the clinical setting and in a number of studies and resources[8,29,68,76,108,123,168] by stretching in a single plane or opposite the line of pull of a specific muscle group. (For a description of the PNF diagonal patterns, refer to Chapter 6.)

CLINICAL TIP

PNF stretching techniques require that a patient has normal innervation and voluntary control of either the shortened muscle (the range-limiting target muscle) or the muscle on the opposite side of the joint. As such, these techniques cannot be used effectively for patients with paralysis or spasticity resulting from neuromuscular diseases or injury. Furthermore, because PNF stretching procedures are designed to affect the contractile elements of muscle, not the noncontractile

connective tissues, they are more appropriate when muscle spasm limits motion and less appropriate for stretching longstanding, fibrotic contractures.

Hold-Relax and Contract-Relax

With the HR and CR procedures,[29,76,108,123,125,126] the range-limiting target muscle is first lengthened to the point of tissue resistance or to the extent that is comfortable for the patient. The patient then performs a *prestretch, end-range, isometric contraction* (for about 5 seconds) followed by *voluntary* relaxation of the range-limiting target muscle. The limb is then passively moved into the new range as the range-limiting muscle is elongated. A sequence for using the HR and CR technique to stretch shortened pectoralis major muscles bilaterally and increase horizontal abduction of the shoulders is illustrated in Figure 4.14.

NOTE: Although the terms CR and HR often are used interchangeably, in classic PNF, the descriptions of the techniques are not identical. Both techniques are performed in diagonal patterns, but in the CR technique, the rotators of the limb are allowed to contract concentrically while all other muscle groups of the diagonal pattern contract isometrically during the prestretch phase of the procedure. In contrast, in the HR technique, the prestretch isometric contraction occurs in all muscles of the diagonal pattern.[126,158]

Practitioners in the clinical and athletic training settings have reported that the HR and CR techniques appear to make passive elongation of muscles more comfortable for a patient than manual passive stretching.[76] A commonly held assumption is that neuromuscular relaxation, reflected by a decrease in EMG activity, possibly as the result of autogenic inhibition, occurs following the sustained, *prestretch,* isometric contraction of the muscle to be lengthened.[102,125,126] Some investigators[49,108] have challenged this assumption, attributing the gains in flexibility to the viscoelastic properties of the muscle-tendon unit. Their studies revealed evidence of a postcontraction sensory discharge (increased EMG activity) in the range-limiting muscle, suggesting that there was lingering tension in the muscle after the prestretch isometric contraction and that the range-limiting muscle was not reflexively relaxed prior to stretch. However the results of another study[30] indicated no evidence of a postcontraction elevation in EMG activity with the HR or CR techniques.

In light of the mixed evidence about the degree of neuromuscular relaxation occurring, practitioners must determine the effectiveness of the HR or CR techniques based on the responses of their patients.

PRECAUTION: It is not necessary for the patient to perform a maximal isometric contraction of the range-limiting target muscle prior to stretch. Multiple repetitions of maximal prestretch isometric contractions have been shown to result in an acute increase in arterial blood pressure, most notably after

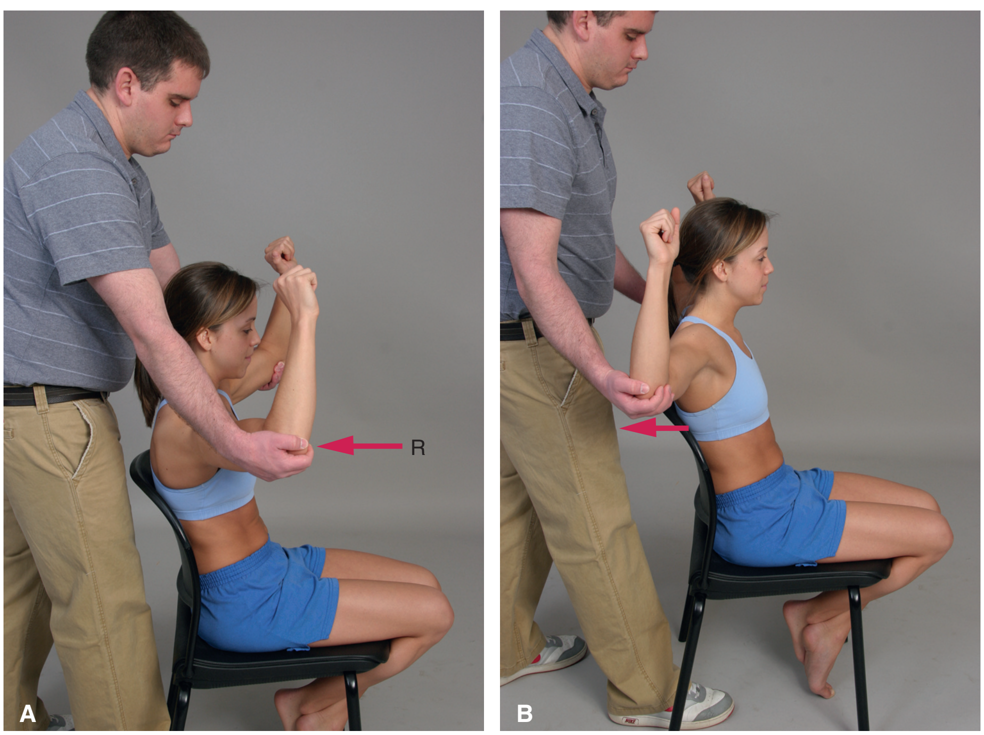

FIGURE 4.14 Hold-relax (HR) procedure to stretch the pectoralis major muscles bilaterally. **(A)** The therapist horizontally abducts the shoulders bilaterally to a comfortable position. The patient isometrically contracts the pectoralis major muscles against the therapist's resistance for about 5 to 10 seconds. **(B)** The patient relaxes voluntarily, and the therapist passively lengthens the pectoralis major muscles by horizontally abducting the shoulders into the newly gained range. After a 10-second rest with the muscles maintained in a comfortably lengthened position, the entire sequence is repeated several times.

the third repetition.[31] To minimize the adverse effects of the Valsalva maneuver (elevation in blood pressure associated with a high-intensity effort), have the patient breathe regularly while performing *submaximal* (low-intensity) isometric contractions held for about 5 seconds with each repetition of the HR or CR procedure. From a practical perspective, a submaximal contraction is also easier for the therapist to control if the patient is strong.

Agonist Contraction

Another PNF stretching technique is the *agonist contraction* (AC) procedure. This term has been used by several authors[30,76,123] but can be misunderstood. The "agonist" refers to the muscle *opposite* the range-limiting target muscle. "Antagonist," therefore, refers to the range-limiting muscle. Think of it as the short muscle (the antagonist) preventing the full movement of the prime mover (the agonist). *Dynamic range of motion* (DROM)[8] and *active stretching*[168] are other terms that have been used to describe the AC procedure.

To perform the AC procedure, the patient *concentrically contracts* (*shortens*) *the muscle opposite the range-limiting muscle* and then holds the end-range position for at least several seconds.[24,30,76,123] The movement of the limb is controlled independently by the patient and is deliberate and slow, not ballistic. In most instances, the shortening contraction is performed without the addition of resistance. For example, if the hip flexors are the range-limiting target muscle group, the patient performs end-range, prone leg lifts by contracting the hip extensors concentrically; the end-range contraction of the hip extensors is held for several seconds. After a brief rest period, the patient repeats the procedure.

Increased muscle length and joint ROM using the AC procedure have been reported. However, when the effectiveness of the AC technique has been compared to static stretching, the evidence is mixed.

FOCUS ON EVIDENCE

Several studies have evaluated the effectiveness of the AC procedure for improving flexibility and ROM. Two studies compared the effect of the AC procedure, referred to as DROM, to static stretching of the hamstrings of healthy subjects who participated in 6-week stretching programs. In one study,[161] DROM was found to be as effective as static stretching, but in the other study,[8] one daily repetition of a 30-second static stretch was almost three times as effective in increasing hamstring flexibility as six repetitions daily of DROM with a 5-second, end-range hold.

In a study of young adults with hypomobile hip flexors and periodic lumbar or lower-quarter pain, investigators compared "active stretching" using the AC procedure to static passive stretching.[168] Both techniques resulted in increased hip extension with no significant difference between the active and passive stretching groups.

In addition to the results of studies on the AC stretching procedure, clinicians have observed the following.

- The AC technique seems to be especially effective when significant muscle guarding restricts muscle lengthening and joint movement and is less effective in reducing chronic contractures.
- This technique is also useful when a patient cannot generate a strong, pain-free contraction of the range-limiting muscle, which must be done during the HR and CR procedures.
- This technique is also useful for initiating neuromuscular control in the newly gained range to re-establish dynamic flexibility.
- The AC technique is least effective if a patient has close to normal flexibility.

PRECAUTIONS: Avoid full-range, ballistic movements when performing concentric contractions of the agonist muscle group. Rest after each repetition to avoid muscle cramping when the agonist is contracting in a very shortened portion of its range.

Classic PNF theory suggests that when the agonist (the muscle opposite the range-limiting muscle) is activated and contracts concentrically, the antagonist (the range-limiting muscle) is reciprocally inhibited, allowing it to relax and lengthen more readily.[125,130] However, the theoretical mechanism of reciprocal inhibition has been substantiated only in animal studies.[127] Evidence of reciprocal inhibition during the AC procedure has not been demonstrated in human subjects[24,127,138] In fact, an increase of EMG activity, not reciprocal inhibition, has been identified in the range-limiting muscle during application of the AC stretching procedure.[30,123]

Hold-Relax with Agonist Contraction

The HR-AC stretching technique combines the HR and AC procedures. The HR-AC technique is also referred to as the CR-AC procedure[24] or slow reversal hold-relax technique.[158] To perform the HR-AC procedure, move the limb to the point that tissue resistance is felt in the range-limiting target muscle; then have the patient perform a resisted, prestretch isometric contraction of the range-limiting muscle *followed* by voluntary relaxation of that muscle and an immediate concentric contraction of the muscle *opposite* the range-limiting muscle.[30,125,158]

For example, to stretch knee flexors, extend the patient's knee to a comfortable, end-range position and then have the patient perform an isometric contraction of the knee flexors against resistance for about 5 seconds. Tell the patient to voluntarily relax and then actively extend the knee as far as possible, holding the newly gained range for several seconds.

FOCUS ON EVIDENCE

Studies comparing two PNF stretching procedures produced differing results. In one study,[52] the HR-AC technique produced a greater increase in ankle dorsiflexion range than did the HR

technique. Both PNF techniques produced a greater increase in range of ankle dorsiflexion than did manual passive stretching. However, in another study,[76] there was no significant difference between the use of the HR and HR-AC techniques.

PRECAUTIONS: Follow the same precautions as described for both the HR and AC procedures.

Integration of Function into Stretching

Importance of Strength and Muscle Endurance

As previously discussed, the strength of soft tissue is altered when it is immoblized for a period of time.[25,115] The magnitude of peak tension produced by muscle decreases, and the tensile strength of noncontractile tissues decreases. A muscle group that has been overstretched because its opposing muscle group has been in a shortened state for an extended period of time also becomes weak.[87,96,97] Therefore, it is critical to begin low-load resistance exercises to improve muscle performance (strength and endurance) as early as possible in a stretching program.

Initially, it is important to place emphasis on developing neuromuscular control and strength of the agonist, the muscle group opposite the muscle that is being stretched. For example, if the elbow flexors are the range-limiting muscle group, emphasize contraction of the elbow extensors in the gained range. Complement stretching the hamstrings to reduce a knee flexion contracture by using the quadriceps in the new range. Early use of the agonist enables the patient to elongate the hypomobile structures actively and use the recently gained ROM.

As ROM approaches a "normal" or functional level, the muscles that were shortened and then stretched must also be strengthened to maintain an appropriate balance of strength between agonists and antagonists throughout the ROM. Manual and mechanical resistance exercises are effective ways to load and strengthen muscles, but functional weight-bearing activities, such as those mentioned below also strengthen antigravity muscle groups.

Use of Increased Mobility for Functional Activities

As mentioned previously, gains in flexibility and ROM achieved as the result of a stretching program are transient, lasting only about 4 weeks after cessation of stretching.[166] The most effective means of achieving permanent increases in ROM and reducing functional limitations is to integrate functional activities into a stretching program to use the gained range on a regular basis. Use of functional activities to maintain mobility lends diversity and interest to a stretching program.

Active movements should be within the pain-free ROM. Examples of movements of the upper or lower extremities or spine that are components of daily activities include reaching, grasping, turning, twisting, bending, pushing, pulling, and squatting to name just a few. As soon as even small increases in tissue extensibility and ROM have been achieved, have the patient use the gained range by performing motions that *simulate* functional activities. Later, have the patient use all of the available ROM while actually doing specific functional tasks.

Functional movements that are practiced should complement the stretching program. For example, if a patient has been performing stretching exercises to increase shoulder mobility, have the patient fully use the available ROM by reaching as far as possible behind the back and overhead when grooming or dressing or by reaching for or placing objects on a high shelf (Fig. 4.15). Gradually increase the weight of objects placed on or removed from a shelf to strengthen shoulder musculature simultaneously.

If the focus of a stretching program has been to increase knee flexion after removal of a long-leg cast, emphasize flexing both knees before standing up from a chair or when

FIGURE 4.15 (A, B) Stretching-induced gains in ROM are used during daily activities.

stooping to pick up an object from the floor. These weight-bearing activities also strengthen the quadriceps that became weak while the leg was immobilized and the quadriceps were held in a shortened position.

Procedural Guidelines for Application of Stretching Interventions

The following guidelines are central to the development and implementation of stretching interventions. The results of an examination and evaluation of a patient's status determine the need for and types of stretching procedures that will be most effective in a patient's plan of care. This section identifies general guidelines to be addressed before, during, and after stretching procedures as well as guidelines specific to the application of manual stretching. Special considerations for teaching self-stretching exercises and using mechanical stretching devices are listed in Boxes 4.7 and 4.8.

Examination and Evaluation of the Patient

- Carefully review the patient's history and perform a thorough systems review.
- Select and perform appropriate tests and measurements. Determine the ROM available in involved and adjacent joints and if either active or passive mobility is impaired.
- Determine if hypomobility is related to other impairments of body structure or function and if it is causing activity limitations (functional limitations) or participation restrictions (disability).
- Ascertain if—and if so, which—soft tissues are the source of the impaired mobility. In particular, differentiate between joint capsule, periarticular, noncontractile tissue, and muscle length restrictions as the cause of limited ROM. Be sure to assess joint play and fascial mobility.
- Evaluate the irritability of the involved tissues and determine their stage of healing. When moving the patient's extremities or spine, pay close attention to the patient's reaction to movements. This not only helps identify the stage of healing of involved tissues, it helps determine the probable dosage (such as intensity and duration) of stretch that stays within the patient's comfort range.
- Assess the underlying strength of muscles in which there is limitation of motion and realistically consider the value of stretching the range-limiting structures. An individual must have the capability of developing adequate strength to control and use the new ROM safely.
- Be sure to determine what outcome goals (i.e., functional improvements) the patient is seeking to achieve as the result of the intervention program and determine if those goals are realistic.
- Analyze the impact of any factors that could adversely affect the projected outcomes of the stretching program.

BOX 4.7 Special Considerations for Teaching Self-Stretching Exercises

- Be sure to carefully teach the patient all elements of self-stretching procedures, including appropriate alignment and stabilization, intensity, duration, and frequency of stretching. Because many self-stretching exercises are performed using a portion of the body weight as the stretch force (by moving the body over a fixed distal segment), emphasize the importance of performing a slow, sustained stretch, not a ballistic stretch that creates momentum and may lengthen but can potentially injure hypomobile soft tissues.
- Make sure the patient is taught to carry out stretching exercises on a firm, stable, comfortable surface to maintain proper alignment.
- Supervise the patient and make suggestions or corrections to be certain the patient performs each exercise using safe biomechanics that protect joints and ligaments, especially at the end of the ROM. Pay particular attention to maintaining postural alignment and effective stabilization. For example, while self-stretching the hamstrings in a long-sitting position or while standing with one leg resting on a table, be sure that the patient knows to keep the thoracolumbar segments of the spine in extension and to bend forward at the hips to prevent posterior pelvic tilt and overstretch of the low back.
- Emphasize the importance of warming up the tissues with low-intensity, rhythmic activities, such as cycling, prior to stretching. Stretching should not be the first activity in an exercise routine, because cold tissue is more brittle and more easily torn.
- If appropriate and possible, teach the patient how to incorporate neuromuscular inhibition techniques, such as the hold-relax (HR) procedure, independently into selected stretching exercises.
- Provide written instructions with illustrations to which the patient can refer when independently performing the self-stretching exercises.
- Demonstrate how items commonly found around the house, such as a towel, belt, broomstick, or homemade weight, can be used to assist with stretching activities.
- Emphasize the importance of using the gained ROM during appropriately progressed functional activities.

BOX 4.8 Special Considerations for Use of Mechanical Stretching Devices

- Become thoroughly familiar with the manufacturer's product information.
- Become familiar with stretching protocols recommended by the manufacturer; seek out research studies that provide evidence of the efficacy of the equipment or protocols.
- Determine if modifying a suggested protocol is warranted to meet your patient's needs. For example, should the suggested intensity of stretch or recommended wearing time (duration and frequency) be modified?
- Check the fit of a device before sending it home with a patient. Teach the patient how to apply and safely adjust the device and how to maintain it in good working order. Be sure that the patient knows who to contact if the equipment appears to be defective.
- Teach the patient where and how to inspect the skin to detect areas of excessive pressure from the stretching device and potential skin irritation.
- If the mechanical stretching device is "homemade," such as a cuff weight, check to see if the equipment is safe and effective.
- Have the patient keep a daily record of using the stretching device.
- Re-examine and re-evaluate the patient and equipment periodically to determine the effectiveness of the mechanical stretching program and to modify and progress the program as necessary.
- Be sure the patient complements the use of mechanical stretching with active exercises.

Preparation for Stretching

- Review the goals and desired outcomes of the stretching program with the patient. Obtain the patient's consent to initiate treatment.
- Select the stretching techniques that will be most effective and efficient.
- Warm up the soft tissues to be stretched by the application of local heat or by active, low-intensity exercises. Warming up tight structures may increase their extensibility and may decrease the risk of injury from stretching.
- Have the patient assume a comfortable, stable position that allows the correct plane of motion for the stretching procedure. *The direction of stretch is exactly opposite the direction of the joint or muscle restriction.*
- Explain the procedure to the patient and be certain he or she understands.
- Free the area to be stretched of any restrictive clothing, bandages, or splints.
- Explain to the patient that it is important to be as relaxed as possible. Also, explain that the stretching procedures are geared to his or her tolerance level.

Application of Manual Stretching Procedures

- Move the extremity slowly through the free range to the point of tissue restriction.
- Grasp the areas proximal and distal to the joint in which motion is to occur. The grasp should be firm but not uncomfortable for the patient. Use padding, if necessary, in areas with minimal subcutaneous tissue, reduced sensation, or over a bony surface. Use the broad surfaces of your hands to apply all forces.
- Firmly stabilize the proximal segment (manually or with equipment) and move the distal segment.
- To stretch a multijoint muscle, stabilize either the proximal or distal segment to which the range-limiting muscle attaches. Stretch the muscle over one joint at a time and then over all joints simultaneously until the optimal length of soft tissues is achieved. To minimize compressive forces in small joints, stretch the distal joints first and proceed proximally.
- Consider incorporating a prestretch, isometric contraction of the range-limiting muscle (the hold-relax procedure) theoretically designed to relax the muscle reflexively prior to stretching it.
- To avoid joint compression during the stretching procedure, apply gentle (grade I) distraction to the moving joint.
- Apply a low-intensity stretch in a slow, sustained manner. Remember, the direction of the stretching movement is directly *opposite* the line of pull of the range-limiting muscle. Ask the patient to assist you with the stretch, or apply a passive stretch to lengthen the tissues. Take the hypomobile soft tissues to the point of firm tissue resistance and then move just beyond that point. The force must be enough to place tension on soft tissue structures but not so great as to cause pain or injure the structures. The patient should experience a *pulling sensation*, but not pain, in the structures being stretched. When stretching adhesions of a tendon within its sheath, the patient may experience a "stinging" sensation.
- Maintain the stretched position for 30 seconds or longer. During this time, the tension in the tissues should slowly decrease. When tension decreases, move the extremity or joint a little farther to progressively lengthen the hypomobile tissues.
- Gradually release the stretch force and allow the patient and therapist to rest momentarily while maintaining the range-limiting tissues in a comfortably elongated position. Then repeat the sequence several times.

- If the patient does not seem to tolerate a sustained stretch, use several very slow, gentle, intermittent stretches with the muscle in a lengthened position.
- If deemed appropriate, apply selected soft tissue mobilization procedures, such as fascial massage or cross-fiber friction massage, at or near the sites of adhesion during the stretching maneuver.

CLINICAL TIP

Do not attempt to gain the full range in one or two treatment sessions. Resolving mobility impairment is a slow, gradual process. It may take several weeks of stretching to see significant results. Between stretching sessions, it is important to use the newly increased range to maintain what has been gained.

After Stretching

- Apply cold to the soft tissues that have been stretched and allow these structures to cool in a lengthened position. Cold may minimize poststretch muscle soreness that can occur as the result of microtrauma during stretching. When soft tissues are cooled in a lengthened position, increases in ROM are more readily maintained.[78,111]
- Regardless of the type of stretching intervention used, have the patient perform active ROM and strengthening exercises through the gained range immediately after stretching. With your supervision and feedback, have the patient use the gained range by performing simulated functional movement patterns that are part of daily living, occupational, or recreational tasks.
- Develop a balance in strength in the antagonistic muscles in the new range, so there is adequate neuromuscular control and stability as flexibility increases.

Precautions for Stretching

There are a number of general precautions that apply to all forms of stretching interventions. In addition, some special precautions must be taken when advising patients about stretching exercises that are part of community-based fitness programs or commercially available exercise products marketed to the general public.

General Precautions

- Do not passively force a joint beyond its normal ROM. Remember, normal (typical) ROM varies among individuals. In adults, flexibility is greater in women than in men.[172] When treating older adults, be aware of age-related changes in flexibility.

FOCUS ON EVIDENCE

Some studies suggest that flexibility decreases with age, particularly when coupled with decreased activity levels.[3,4,98] However, the results of a study of more than 200 adults ages 20 to 79 who regularly exercised demonstrated that hamstring length did not significantly decrease with age.[172]

- Use extra caution in patients with known or suspected osteoporosis due to disease, prolonged bed rest, age, or prolonged use of steroids.
- Protect newly united fractures; be certain there is appropriate stabilization between the fracture site and the joint in which the motion takes place.
- Avoid vigorous stretching of muscles and connective tissues that have been immobilized for an extended period of time. Connective tissues, such as tendons and ligaments, lose their tensile strength after prolonged immobilization.[96] High- intensity, short-duration stretching procedures tend to cause more trauma and resulting weakness of soft tissues than low-intensity, long-duration stretch.
- Progress the dosage (intensity, duration, and frequency) of stretching interventions gradually to minimize soft tissue trauma and postexercise muscle soreness. If a patient experiences joint pain or muscle soreness lasting more than 24 hours after stretching, too much force has been used during stretching, causing an inflammatory response. This, in turn, causes increased scar tissue formation. Patients should experience no more residual discomfort than a transitory feeling of tenderness.
- Avoid stretching edematous tissue, as it is more susceptible to injury than normal tissue. Continued irritation of edematous tissue usually causes increased pain and edema.
- Avoid overstretching weak muscles, particularly those that support body structures in relation to gravity.

Special Precautions for Mass-Market Flexibility Programs

In an effort to develop and maintain a desired level of fitness, many people, young and old, participate in physical conditioning programs at home or in the community. Self-stretching exercises are an integral component of these programs. As a result, individuals frequently learn self-stretching procedures in fitness classes or from popular videos or television programs. Although much of the information in these resources is usually safe and accurate, there may be some errors and potential problems in flexibility programs designed for the mass market.

Common Errors and Potential Problems

Nonselective or poorly balanced stretching activities. General flexibility programs may include stretching regions of the body that are already mobile or even hypermobile but

may neglect regions that are tight from faulty posture or inactivity. For example, in the sedentary population, some degree of hypomobility tends to develop in the hip flexors, trunk flexors, shoulder extensors and internal rotators, and scapular protractors from sitting in a slumped posture. Yet, many commercially available flexibility routines overemphasize exercises that stretch posterior muscle groups, already overstretched, and fail to include exercises to stretch the tight anterior structures. Consequently, faulty postures may worsen rather than improve.

Insufficient warm-up. Individuals involved in flexibility programs often fail to warm up prior to stretching.

Ineffective stabilization. Programs often lack effective methods of self-stabilization. Therefore, an exercise may fail to stretch the intended tight structures and may transfer the stretch force to structures that are already mobile or even hypermobile.

Use of ballistic stretching. Although a less common problem than in the past, some exercise routines still demonstrate stretches using ballistic maneuvers. Because this form of stretching is not well controlled, it increases the likelihood of postexercise muscle soreness and significant injury to soft tissues.

Excessive intensity. The phrase "*no pain, no gain*" is often used inappropriately as the guideline for intensity of stretch. An effective flexibility routine should be progressed gradually and should not cause pain or excessive stress to tissues.

Abnormal biomechanics. Some popular stretching exercises do not respect the biomechanics of the region. For example, the "hurdler's" stretch is designed to stretch unilaterally the hamstrings of one lower extremity and the quadriceps of the opposite extremity but imposes unsafe stresses on the medial capsule and ligaments of the flexed knee.

Insufficient information about age-related differences. One flexibility program does not fit all age groups. As a result of the normal aging process, mobility of connective tissues diminishes.[3,4,82] Consequently, elderly individuals, whose physical activity level has diminished with age, typically exhibit less flexibility than young adults. Even an adolescent after a growth spurt temporarily exhibits restricted flexibility, particularly in two-joint muscle groups. Flexibility programs marketed to the general public may not be sensitive to these normal, age-related differences in flexibility and may foster unrealistic expectations.

Strategies for Risk Reduction

- Whenever possible, assess the appropriateness and safety of exercises in a "prepackaged" flexibility program.
- If a patient you are treating is participating in a community-based fitness class, review the exercises in the program and determine their appropriateness and safety for your patient.
- Stay up-to-date on current exercise programs, products, and trends by monitoring the content and safety and your patient's use of home exercise videotapes.
- Determine whether a class or video is geared for individuals of the same age or with similar pathological conditions.
- Eliminate or modify those exercises that are inconsistent with the intervention plan you have developed for your patient.
- See that the flexibility program maintains a balance of mobility between antagonistic muscle groups and emphasizes stretching those muscle groups that often become shortened with age, faulty posture, or sedentary lifestyle.
- Teach your patient basic principles of self-stretching and how to apply those principles to select safe and appropriate stretching exercises and to avoid those that perpetuate impairments or have no value.
- Make sure your patient understands the importance of warming up prior to stretching. Give suggestions on how to warm up before stretching.
- Be certain that the patient knows how to provide effective self-stabilization to isolate stretch to specific muscle groups.
- Teach your patient how to determine the appropriate intensity of stretch; be sure your patient knows that, at most, postexercise muscle soreness should be mild and last no more than 24 hours.

Adjuncts to Stretching Interventions

Practitioners managing patients with structural or functional impairments, including chronic pain, muscle guarding or imbalances, and restricted mobility, may find it useful to integrate complementary therapies that address the body, mind, and spirit, such as relaxation training, Pilates exercises, yoga, or tai chi into a patient's plan of care to improve function and quality of life. Other interventions that are useful adjuncts to a stretching program include superficial or deep heat, cold, massage, biofeedback, and joint traction.

Complementary Exercise Approaches

Relaxation Training

Relaxation training, using methods of general relaxation (total body relaxation), has been used for many years by a variety of practitioners[51,55,79,136,156,] to help patients learn to relieve or reduce pain, muscle tension, anxiety or stress, and associated physical impairments or medical conditions including tension headaches, high blood pressure, and respiratory distress. Volumes have been written by health professionals from many disciplines on topics such as chronic pain management, progressive relaxation, biofeedback, stress and anxiety management, and imagery. A brief overview of techniques is presented in this section.

There are a number of physiological, behavioral, cognitive, and emotional responses that occur during total body relaxation.[156] These key indicators are summarized in Box 4.9.

BOX 4.9 Indicators of Relaxation

- Decreased muscle tension
- Lowered heart and respiratory rates and blood pressure
- Increased skin temperature in the extremities associated with vasodilation
- Constricted pupils
- Little to no body movement
- Eyes closed and flat facial expression
- Jaw and hands relaxed with palms open
- Decreased distractibility

Common Elements of Relaxation Training

Relaxation training involves a reduction in muscle tension in the entire body or the region that is painful or restricted by using conscious effort and thought. Training occurs in a quiet environment with low lighting and soothing music or an auditory cue on which the patient may focus. The patient performs deep breathing exercises or visualizes a peaceful scene. When giving instructions, the therapist uses a soft tone of voice.

Examples of Approaches to Relaxation Training

Autogenic training. This approach, advocated by Schultz and Luthe[136] and Engle,[51] involves conscious relaxation through autosuggestion and a progression of exercises as well as meditation.

Progressive relaxation. This technique, pioneered by Jacobson,[79] uses systematic, distal to proximal progression of voluntary contraction and relaxation of muscles. It is sometimes incorporated into childbirth education.

Awareness through movement. The system of therapy developed by Feldenkrais[55] combines sensory awareness, movements of the limbs and trunk, deep breathing, conscious relaxation procedures, and self-massage to alter muscle imbalances and abnormal postural alignment to remediate muscle tension and pain.

Sequence for Progressive Relaxation Techniques

- Place the patient in a quiet area and in a comfortable position, and be sure that restrictive clothing is loosened.
- Have the patient breathe in a deep, relaxed manner.
- Ask the patient to contract the distal musculature in the hands or feet voluntarily for several (5 to 7) seconds and then consciously relax those muscles for 20 to 30 seconds.
- Suggest that the patient try to feel a sense of heaviness in the hands or feet and a sense of warmth in the muscles just relaxed.
- Progress to a more proximal area of the body and have the patient actively contract and actively relax the more proximal musculature. Eventually have the patient isometrically contract and consciously relax the entire extremity.
- Suggest to the patient that he or she should feel a sense of relaxation and warmth throughout the entire limb and eventually throughout the whole body.

Pilates

Pilates is an approach to exercise that combines Western theories of biomechanics, core stability, and motor control with Eastern theories of the interaction of body, mind, and spirit.[5] Components of a Pilates exercise session typically include deep breathing and core stabilization exercises, focus on activation and relaxation of specific muscle groups, posture control and awareness training, strength training (primarily using body weight as resistance), balance exercises, and flexibility exercises.[142]

Although Pilates training often is part of community-based fitness programs for healthy adults, increasingly, therapists are incorporating elements of Pilates into individualized intervention programs for patients with a variety of diagnoses. Despite limited research, the effects and benefits of Pilates exercises on function (including improved flexiblity, strength, and pain control) and the quality of life in healthy individuals[137] and those with impairments are beginning to be documented.[86,134]

Heat

Warming up prior to stretching is an important element of rehabilitation and fitness programs. It is well documented in human and animal studies that as intramuscular temperature increases, the extensibility of contractile and noncontractile soft tissues likewise increases. In addition, as the temperature of muscle increases, the amount of force required and the time the stretch force must be applied decrease.[94,95,131,164] There is also a decrease in the rate of firing of the type II efferents from the muscle spindles and an increase in the sensitivity of the GTO, which makes it more likely to fire.[58] In turn, it is believed that when tissues relax and more easily lengthen, stretching is associated with less muscle guarding and is more comfortable for the patient.[94,95]

CLINICAL TIP

Although stretching is often thought of as a warm-up activity performed prior to vigorous exercise,[139] an appropriate warm-up, typically through low- intensity active exercise, must be carried out *in preparation* for stretching.

Methods of Warm-Up

Superficial heat (hot packs, paraffin) or deep-heating modalities (ultrasound, shortwave diathermy) provide different mechanisms to heat tissues.[113,129] These thermal agents are used primarily to heat small areas such as individual joints, muscle groups, or tendons and may be applied prior to or during the stretching procedure.[6,47,89,131] There is no consensus as to whether heating modalities should be applied prior to or during the stretching procedure.

Low-intensity, active exercises, which generally increase circulation and core body temperature, also have been used as a mechanism to warm up large muscle groups prior to

stretching.[44,61,89,141] Some common warm-up exercises are a brief walk, nonfatiguing cycling on a stationary bicycle, use of a stair-stepping machine, active heel raises, or a few minutes of active arm exercises.

Effectiveness of Warm-up Methods

The use of heat alone (a thermal agent or warm-up exercises) without stretching has been shown to have either little or no effect on improving muscle flexibility.[18,44,71,143] Although some evidence indicates that heat combined with stretching produces greater long-term gains in tissue length than stretching alone,[46,47] the results of other studies have shown comparable improvement in ROM with no significant differences between conditions.[44,61,71,89,148]

Cold

The application of cold prior to stretching (cryostretching) compared to heat has been studied.[90,148] Advocates suggest its use to decrease muscle tone and make the muscle less sensitive during stretch in healthy subjects[67] and in patients with spasticity or rigidity secondary to upper motor neuron lesions.[158] The use of cold immediately after soft tissue injury effectively decreases pain and muscle spasm.[90] However, once soft tissue healing and scar formation begin, cold makes healing tissues less extensible and more susceptible to microtrauma during stretching.[35,94] Cooling soft tissues in a lengthened position *after* stretching has been shown to promote more lasting increases in soft tissue length and minimize poststretch muscle soreness.[95]

CLINICAL TIP

The authors of this text recommend that cold be applied to injured soft tissues during the first 24 to 48 hours after injury to minimize swelling, muscle spasm, and pain. Remember, stretching is contraindicated in the presence of inflammation that occurs during the acute phase of tissue healing (see Chapter 10). When inflammation subsides and stretching is indicated, the authors advocate warming soft tissues prior to or during a stretching maneuver. After stretching, cold should be applied to soft tissues held in a lengthened position to minimize poststretch muscle soreness and to promote longer-lasting gains in ROM.

Massage

Massage for Relaxation

Local muscle relaxation can be enhanced by massage, particularly with light or deep stroking techniques.[41,147] In some approaches to stress and anxiety or pain management, self-massage, using light stroking techniques (effleurage), is performed during the relaxation process.[55] In sports and conditioning programs,[10,147] massage has been used for general relaxation purposes or to enhance recovery after strenuous physical activity, although the efficacy of the latter is not well founded.[154] Because massage has been shown to increase circulation to muscles and decrease muscle spasm, it is a useful adjunct to stretching exercises.

Soft Tissue Mobilization/Manipulation Techniques

Another broad category of massage is soft tissue mobilization/manipulation. Although these techniques involve various forms of deep massage, the primary purpose is not relaxation but rather, increasing the mobility of adherent or shortened connective tissues including fascia, tendons, and ligaments.[22]

There are many techniques and explanations as to their effects on connective tissues, including the mechanical effects of stress and strain. Stresses are applied long enough for creep and stress-relaxation of tissues to occur. With *myofascial massage*,[22,100] stretch forces are applied across fascial planes or between muscle and septae. With *friction massage*,[37,75,147] deep circular or cross-fiber massage is applied to break up adhesions or minimize rough surfaces between tendons and their synovial sheaths. Friction massage is also used to increase the mobility of scar tissue in muscle as it heals. Theoretically, it applies stresses to scar tissue as it matures to align collagen fibers along the lines of stress for normal mobility. These forms of connective tissue massage as well as many other approaches and techniques of soft tissue mobilization are useful interventions for patients with restricted mobility.

Biofeedback

Biofeedback is another tool to help a patient learn and practice the process of relaxation. Biofeedback is also a useful means to help a patient learn how to activate a muscle, rather than relax it, such as when learning how to perform quadriceps setting exercises after knee surgery.

A patient, if properly trained, can electronically monitor and learn to reduce the amount of tension in muscles, as well as heart rate and blood pressure, through biofeedback instrumentation.[51,156] Through visual or auditory feedback, a patient can begin to sense or feel what muscle relaxation is. By reducing muscle tension, pain can be decreased and flexibility increased.

Joint Traction or Oscillation

Slight manual distraction of joint surfaces prior to or in conjunction with joint mobilization/manipulation techniques or stretching a muscle-tendon unit can be used to inhibit joint pain and spasm of muscles around a joint (see Chapter 5).[37,75,83] Pendular motions of a joint use the weight of the limb to distract the joint surfaces and simultaneously oscillate and relax the limb. The joint may be further distracted by adding a 1- or 2-lb weight to the extremity, which causes a stretch force on joint tissues.

Manual Stretching Techniques in Anatomical Planes of Motion

As with the ROM exercises described in Chapter 3, the manual stretching techniques in this section are described with the patient in a *supine* position. Alternative patient positions, such as prone or sitting, are indicated for some motions and are noted when necessary. Manual stretching procedures in an aquatic environment are described in Chapter 9.

Effective manual stretching techniques require adequate stabilization of the patient and sufficient strength and good body mechanics of the therapist. Depending on the size (height and weight) of the therapist and the patient, modifications in the patient's position and suggested hand placements for stretching or stabilization may have to be made by the therapist.

Each description of a stretching technique is identified by the anatomical plane of motion that is to be increased followed by a notation of the muscle group being stretched. Limitations in functional ROM usually are caused by shortening of multiple muscle groups and periarticular structures, and they affect movement in combined (as well as anatomical) planes of motion. In this situation, however, stretching multiple muscle groups simultaneously using diagonal patterns (i.e., D_1 and D_2 flexion and extension of the upper or lower extremities as described in Chapter 6) is *not* recommended and, therefore, is not described in this chapter. The authors believe that combined, diagonal patterns are appropriate for maintaining available ROM with passive and active exercises and increasing strength in multiple muscle groups but are ineffective for *isolating* a stretch force to specific muscles or muscle groups of the extremities that are shortened and restricting ROM. Special considerations for each region being stretched are also noted in this section.

Prolonged passive stretching techniques using mechanical equipment are applied using the same points of stabilization as manual stretching. The stretch force is applied at a lower intensity and is applied over a much longer period than with manual stretching. The stretch force is provided by weights or splints rather than the strength or endurance of a therapist. The patient is stabilized with belts, straps, or counterweights.

NOTE: Manual stretching procedures for the musculature of the cervical, thoracic, and lumbar spine may be found in Chapter 16. Selected self-stretching techniques of the extremities and spine that a patient can do without assistance from a therapist are not described in this chapter. These exercises for each joint of the extremities can be found in Chapters 16 through 22.

Upper Extremity Stretching

The Shoulder: Special Considerations

Many muscles involved with shoulder motion attach to the scapula rather than the thorax. Therefore, when most muscles of the shoulder girdle are stretched, it is imperative to stabilize the scapula. Without scapular stabilization the stretch force is transmitted to the muscles that normally stabilize the scapula during movement of the arm. This subjects these muscles to possible overstretching and disguises the true ROM of the glenohumeral joint. Remember:

- When the scapula is stabilized and not allowed to abduct or upwardly rotate, only 120° of shoulder flexion and abduction can occur at the glenohumeral joint.
- The humerus must be externally rotated to gain full ROM of abduction.
- Muscles most apt to become shortened are those that *prevent* full shoulder flexion, abduction, and external rotation. It is rare to find restrictions in structures that prevent shoulder adduction and extension to neutral.

Shoulder Flexion VIDEO 4.2

To increase flexion of the shoulder (stretch the shoulder extensors) (Fig. 4.16).

Hand Placement and Procedure

- Grasp the posterior aspect of the distal humerus, just above the elbow.

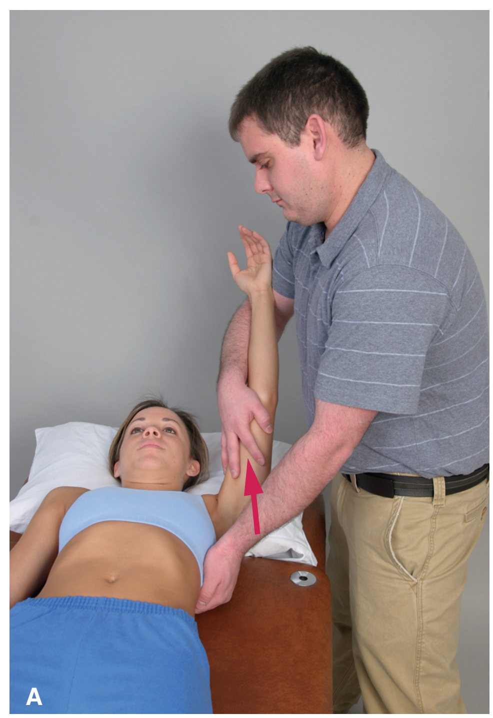

FIGURE 4.16 (A) Hand placement and stabilization of the scapula to stretch the teres major and increase shoulder flexion.

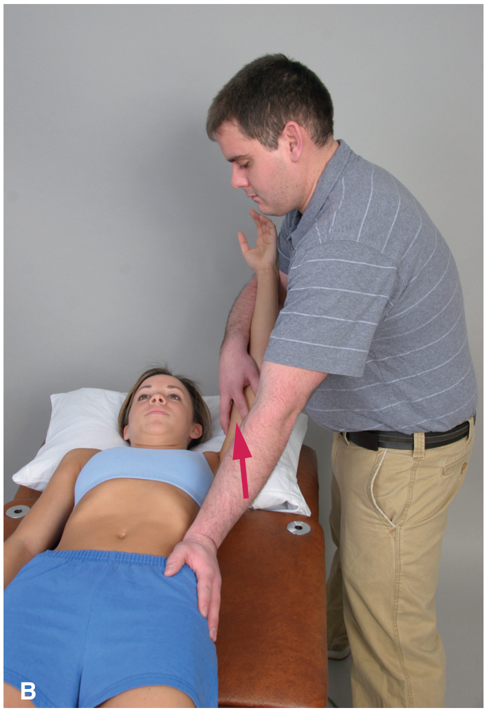

FIGURE 4.16—cont'd (B) Hand placement and stabilization of the pelvis to stretch the latissimus dorsi and increase shoulder flexion.

- Stabilize the axillary border of the scapula to stretch the teres major, or stabilize the lateral aspect of the thorax and superior aspect of the pelvis to stretch the latissimus dorsi.
- Move the patient's arm into full shoulder flexion to elongate the shoulder extensors.

Shoulder Hyperextension VIDEO 4.3

To increase hyperextension of the shoulder (stretch the shoulder flexors) (Fig. 4.17).

Patient Position

Place the patient in a prone position.

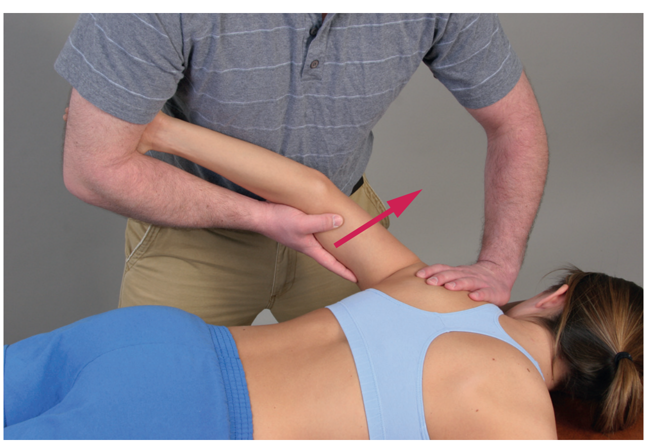

FIGURE 4.17 Hand placement and stabilization of the scapula to increase extension of the shoulder beyond neutral.

Hand Placement and Procedure

- Support the forearm and grasp the distal humerus.
- Stabilize the posterior aspect of the scapula to prevent substitute movements.
- Move the patient's arm into full hyperextension of the shoulder to elongate the shoulder flexors.

Shoulder Abduction

To increase abduction of the shoulder (stretch the adductors) (Fig. 4.18).

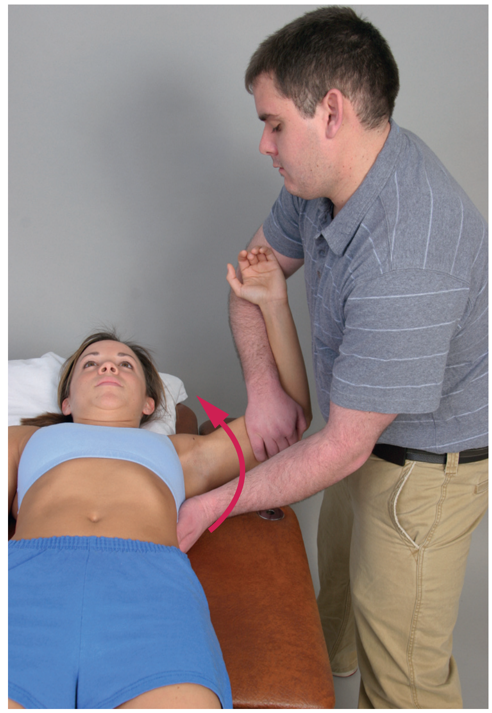

FIGURE 4.18 Hand placement and stabilization of the scapula for the stretching procedure to increase shoulder abduction.

Hand Placement and Procedure

- With the elbow flexed to 90°, grasp the distal humerus.
- Stabilize the axillary border of the scapula.
- Move the patient into full shoulder abduction to lengthen the adductors of the shoulder.

Shoulder Adduction

To increase adduction of the shoulder (stretch the abductors). It is rare when a patient is unable to adduct the shoulder fully to 0° (so the upper arm is at the patient's side). Even if a patient has worn an abduction splint after a soft tissue or joint injury of the shoulder, when he or she is upright the constant pull of gravity elongates the shoulder abductors so the patient can adduct to a neutral position.

Shoulder External Rotation VIDEO 4.4

To increase external rotation of the shoulder (stretch the internal rotators) (Fig. 4.19).

FIGURE 4.19 Shoulder position (slightly abducted and flexed) and hand placement at the mid to proximal forearm to increase external rotation of the shoulder. A folded towel is placed under the distal humerus to maintain the shoulder in slight flexion. The table stabilizes the scapula.

Hand Placement and Procedure

- Abduct the shoulder to a comfortable position—initially 30° or 45° and later to 90° if the glenohumoral (GH) joint is stable—or place the arm at the patient's side.
- Flex the elbow to 90° so the forearm can be used as a lever.
- Grasp the volar surface of the mid-forearm with one hand.
- Stabilization of the scapula is provided by the table on which the patient is lying.
- Externally rotate the patient's shoulder by moving the patient's forearm closer to the table. This fully lengthens the internal rotators.

PRECAUTION: Because it is necessary to apply the stretch forces across the intermediate elbow joint when elongating the internal and external rotators of the shoulder, be sure the elbow joint is stable and pain-free. In addition, keep the intensity of the stretch force very low, particularly in patients with osteoporosis.

Shoulder Internal Rotation

To increase internal rotation of the shoulder (stretch the external rotators) (Fig. 4.20).

FIGURE 4.20 Hand placement and stabilization of the shoulder to increase internal rotation of the shoulder.

Hand Placement and Procedure

- Abduct the shoulder to a comfortable position that allows internal rotation to occur without the thorax blocking the motion (initially to 45° and eventually to 90°).
- Flex the elbow to 90° so the forearm can be used as a lever.
- Grasp the dorsal surface of the midforearm with one hand, and stabilize the anterior aspect of the shoulder and support the elbow with your other forearm and hand.
- Move the patient's arm into internal rotation to lengthen the external rotators of the shoulder.

Shoulder Horizontal Abduction

To increase horizontal abduction of the shoulder (stretch the pectoralis muscles) (Fig. 4.21).

FIGURE 4.21 Hand placement and stabilization of the anterior aspect of the shoulder and chest to increase horizontal abduction of the shoulder past neutral (to stretch the pectoralis major).

Patient Position

To reach full horizontal abduction in the supine position, the patient's shoulder must be at the edge of the table. Begin with the shoulder in 60° to 90° of abduction. The patient's elbow may also be flexed.

Hand Placement and Procedure

- Grasp the anterior aspect of the distal humerus.
- Stabilize the anterior aspect of the shoulder.
- Move the patient's arm below the edge of the table into full horizontal abduction to stretch the horizontal adductors.

NOTE: The horizontal adductors are usually tight bilaterally. Stretching techniques can be applied bilaterally by the therapist, or a bilateral self-stretch can be done by the patient by using a corner or wand (see Figs. 17.30 through 17.32).

Scapular Mobility

To have full shoulder motion, a patient must have normal scapular mobility. (See scapular mobilization/manipulation techniques in Chapter 5.)

The Elbow and Forearm: Special Considerations

Several muscles that cross the elbow, such as the biceps brachii and brachioradialis, also influence supination and pronation of the forearm. Therefore, when stretching the elbow flexors and extensors, the techniques should be performed with the forearm pronated as well as supinated.

Elbow Flexion

To increase elbow flexion (stretch the one-joint elbow extensors).

Hand Placement and Procedure

- Grasp the distal forearm just proximal to the wrist.
- With the arm at the patient's side supported on the table, stabilize the proximal humerus.
- Flex the patient's elbow just past the point of tissue resistance to lengthen the elbow extensors.

To increase elbow flexion with the shoulder flexed (stretch the long head of the triceps) (Fig. 4.22).

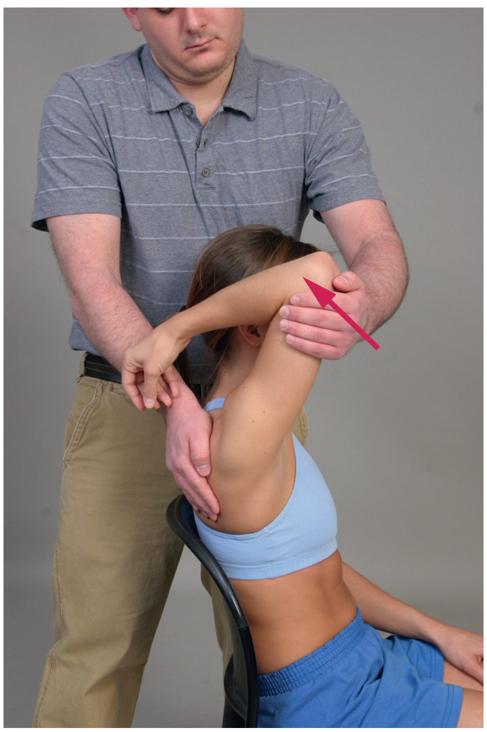

FIGURE 4.22 Hand placement and stabilization to increase elbow flexion with shoulder flexion (to stretch the long head of the triceps brachii).

Patient Position, Hand Placement, and Procedure

- With the patient sitting or lying supine with the arm at the edge of the table, flex the patient's shoulder as far as possible.
- While maintaining shoulder flexion, grasp the distal forearm and flex the elbow as far as possible.

Elbow Extension VIDEO 4.5

To increase elbow extension (stretch the elbow flexors) (Fig. 4.23).

FIGURE 4.23 Hand placement and stabilization of the scapula and proximal humerus for stretching procedures to increase elbow extension.

Hand Placement and Procedure

- Grasp the distal forearm.
- With the upper arm at the patient's side supported on the table, stabilize the scapula and anterior aspect of the proximal humerus.
- Extend the elbow just past the point of tissue resistance to lengthen the elbow flexors.

NOTE: Be sure to do this with the forearm in supination, pronation, and neutral position to stretch each of the elbow flexors.

To increase elbow extension with the shoulder extended (stretch the long head of the biceps).

Patient Position, Hand Placement, and Procedure

- With the patient lying supine close to the side of the table, stabilize the anterior aspect of the shoulder, or with the patient lying prone, stabilize the scapula.
- Pronate the forearm, extend the elbow, and then extend the shoulder.

PRECAUTION: It has been reported that heterotopic ossification (the appearance of ectopic bone in the soft tissues around a joint) can develop around the elbow after traumatic or burn injuries.[50] It is believed that *vigorous, forcible* passive stretching of the elbow flexors may increase the risk of this condition developing. Passive or assisted stretching, therefore, should be applied very gently and gradually in the elbow region. Use of active stretching, such as agonist contraction, might also be considered.

Forearm Supination or Pronation

To increase supination or pronation of the forearm.

Hand Placement and Procedure

- With the patient's humerus supported on the table and the elbow flexed to 90°, grasp the distal forearm.
- Stabilize the humerus.
- Supinate or pronate the forearm just beyond the point of tissue resistance.

- Be sure the stretch force is applied to the radius rotating around the ulna. Do not twist the hand, thereby avoiding stress to the wrist articulations.
- Repeat the procedure with the elbow extended. Be sure to stabilize the humerus to prevent internal or external rotation of the shoulder.

The Wrist and Hand: Special Considerations

VIDEO 4.6

The extrinsic muscles of the fingers cross the wrist joint and, therefore, may influence the ROM of the wrist. Wrist motion may also be influenced by the position of the elbow and forearm, because the wrist flexors and extensors attach proximally on the epicondyles of the humerus.

When stretching the musculature of the wrist, the stretch force should be applied proximal to the metacarpophalangeal (MCP) joints, and the fingers should be relaxed.

Patient Position

When stretching the muscles of the wrist and hand, have the patient sit in a chair adjacent to you with the forearm supported on a table to stabilize the forearm effectively.

Wrist Flexion

To increase wrist flexion.

Hand Placement and Procedure

- The forearm may be supinated, in midposition, or pronated.
- Stabilize the forearm against the table and grasp the dorsal aspect of the patient's hand.
- To elongate the wrist extensors, flex the patient's wrist and allow the fingers to extend passively.
- To further elongate the wrist extensors, extend the patient's elbow.

Wrist Extension

To increase wrist extension (Fig. 4.24).

Hand Placement and Procedure

- Pronate the forearm or place it in midposition, and grasp the patient at the palmar aspect of the hand. If there is a severe wrist flexion contracture, it may be necessary to place the patient's hand over the edge of the treatment table.
- Stabilize the forearm against the table.
- To lengthen the wrist flexors, extend the patient's wrist, allowing the fingers to flex passively.

FIGURE 4.24 Hand placement and stabilization of the forearm for stretching procedure to increase extension of the wrist.

Radial Deviation

To increase radial deviation.

Hand Placement and Procedure

- Grasp the ulnar aspect of the hand along the fifth metacarpal.
- Hold the wrist in midposition.
- Stabilize the forearm.
- Radially deviate the wrist to lengthen the ulnar deviators of the wrist.

Ulnar Deviation

To increase ulnar deviation.

Hand Placement and Procedure

- Grasp the radial aspect of the hand along the second metacarpal, not the thumb.
- Stabilize the forearm.
- Ulnarly deviate the wrist to lengthen the radial deviators.

The Digits: Special Considerations

VIDEO 4.7

The complexity of the relationships among the joint structures and the intrinsic and multijoint extrinsic muscles of the digits requires careful examination and evaluation of the factors that contribute to loss of function in the hand because of limitation of motion. The therapist must determine if a limitation is from restriction of joints, decreased extensibility of the muscle-tendon unit, or adhesions of tendons or ligaments. The digits should always be stretched individually, not simultaneously. If an extrinsic muscle limits motion, lengthen it over one joint while stabilizing the other joints. Then, hold the lengthened position and stretch it over the second joint, and so forth, until normal length is obtained. As noted in Chapter 3, begin the motion with the most distal joint to minimize shearing and compressive stresses to the surfaces of the small joints of the digits. Specific interventions to manage adhesions of tendons are described in Chapter 19.

CMC Joint of the Thumb

To increase flexion, extension, abduction, or adduction of the carpometacarpal (CMC) joint of the thumb.

Hand Placement and Procedure

- Stabilize the trapezium with your thumb and index finger.
- Grasp the first metacarpal (not the first phalanx) with your other thumb and index finger.
- Move the first metacarpal in the desired direction to increase CMC flexion, extension, abduction, and adduction.

MCP Joints of the Digits

To increase flexion, extension, abduction, or adduction of the MCP joints of the digits.

Hand Placement and Procedure

- Stabilize the metacarpal with your thumb and index finger.
- Grasp the proximal phalanx with your other thumb and index finger.
- Keep the wrist in midposition.
- Move the MCP joint in the desired direction for stretch.
- Allow the interphalangeal (IP) joints to flex or extend passively.

PIP and DIP Joints

To increase flexion or extension of the proximal and distal interphalangeal (PIP and DIP) joints.

Hand Placement and Procedure

- Grasp the middle or distal phalanx with your thumb and finger.
- Stabilize the proximal or middle phalanx with your other thumb and finger.
- Move the PIP or DIP joint in the desired direction for stretch.

Stretching Specific Extrinsic and Intrinsic Muscles of the Fingers

Elongation of extrinsic and intrinsic muscles of the hand is described in Chapter 3. To stretch these muscles beyond their available range, the same hand placement and stabilization are used as with passive ROM. The only difference in technique is that the therapist moves each segment into the stretch range.

Lower Extremity Stretching

The Hip: Special Considerations VIDEO 4.8

Because muscles of the hip attach to the pelvis or lumbar spine, the pelvis must always be stabilized when lengthening muscles about the hip. If the pelvis is not stabilized, the stretch force is transferred to the lumbar spine, in which unwanted compensatory motion then occurs.

Hip Flexion

To increase flexion of the hip with the knee flexed (stretch the gluteus maximus).

Hand Placement and Procedure

- Flex the hip and knee simultaneously.
- Stabilize the opposite femur in extension to prevent posterior tilt of the pelvis.
- Move the patient's hip and knee into full flexion to lengthen the one-joint hip extensor.

Hip Flexion with Knee Extension

To increase flexion of the hip with the knee extended (stretch the hamstrings) (Fig. 4.25 A and B).

Hand Placement and Procedure

- With the patient's knee fully extended, support the patient's lower leg with your arm or shoulder.

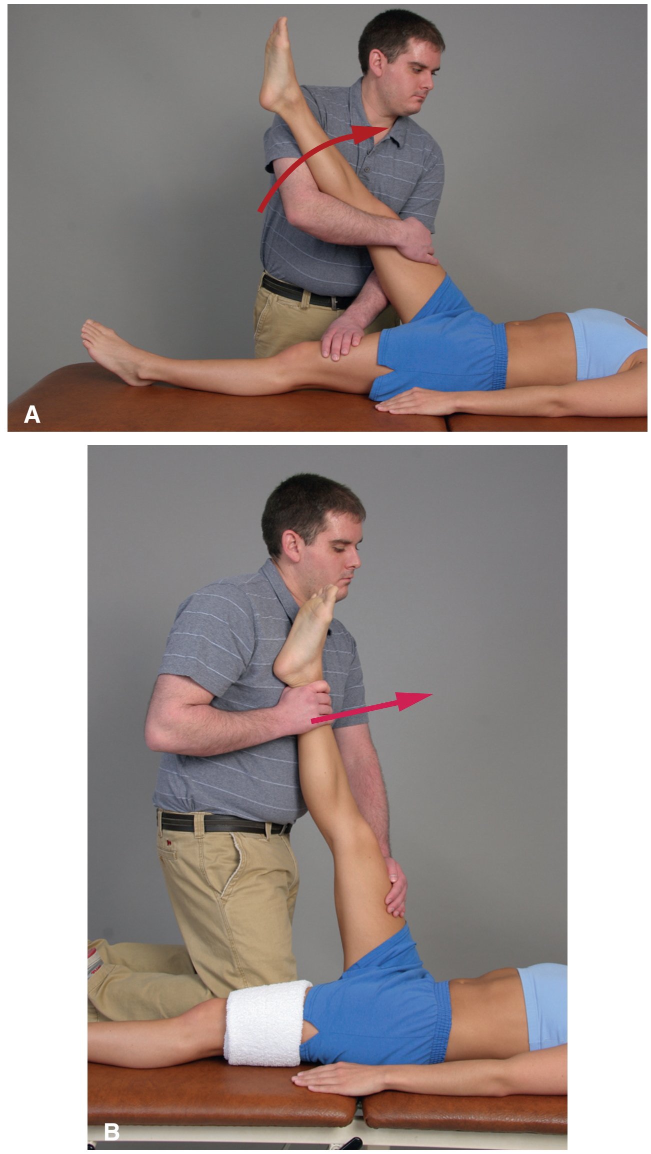

FIGURE 4.25 Hand placement and stabilization of the opposite femur to stabilize the pelvis and low back for stretching procedures to increase hip flexion with knee extension (stretch the hamstrings) with the therapist **(A)** standing by the side of the table or **(B)** kneeling on the table.

- Stabilize the opposite extremity along the anterior aspect of the thigh with your other hand or a belt or with the assistance of another person.
- With the knee at 0° extension and the hip in neutral rotation, flex the hip as far as possible.

NOTE: Externally rotate the hip prior to hip flexion to isolate the stretch force to the medial hamstrings and internally rotate the hip to isolate the stretch force to the lateral hamstrings.

Alternative Therapist Position

Kneel on the mat and place the patient's heel or distal tibia against your shoulder (see Fig. 4.25 B). Place both of your

hands along the anterior aspect of the distal thigh to keep the knee extended. The opposite extremity is stabilized in extension by a belt or towel around the distal thigh and held in place by the therapist's knee.

Hip Extension VIDEO 4.9

To increase hip extension (stretch the iliopsoas) (Fig. 4.26).

FIGURE 4.26 Hand placement and stabilization of the pelvis to increase extension of the hip (stretch the iliopsoas) with the patient lying supine. Flexing the knee when in this position also elongates the rectus femoris.

Patient Position

Have the patient positioned close to the edge of the treatment table so the hip being stretched can be extended beyond neutral. The opposite hip and knee are flexed toward the patient's chest to stabilize the pelvis and spine.

Hand Placement and Procedure

- Stabilize the opposite leg against the patient's chest with one hand, or if possible, have the patient assist by grasping around the thigh and holding it to the chest to prevent an anterior tilt of the pelvis during stretching.
- Move the hip to be stretched into extension or hyperextension by placing downward pressure on the anterior aspect of the distal thigh with your other hand. Allow the knee to extend so the two-joint rectus femoris does not restrict the range.

Alternate Position

The patient can lie prone (Fig. 4.27).

Hand Placement and Procedure

- Support and grasp the anterior aspect of the patient's distal femur.
- Stabilize the patient's buttocks to prevent movement of the pelvis.
- Extend the patient's hip by lifting the femur off the table.

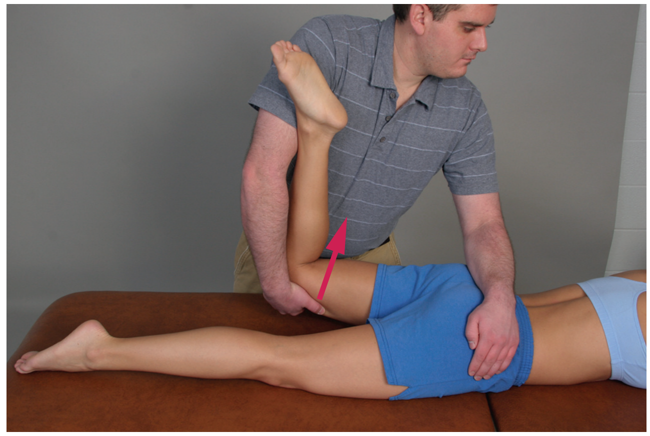

FIGURE 4.27 Hand placement and stabilization to increase hyperextension of the hip with the patient lying prone.

Hip Extension with Knee Flexion

To increase hip extension and knee flexion simultaneously (stretch the rectus femoris).

Patient Position

Use either of the positions previously described for increasing hip extension in the supine or prone positions (see Figs. 4.26 and 4.27).

Hand Placement and Procedure

- With the hip held in full extension on the side to be stretched, move your hand to the distal tibia and gently flex the knee of that extremity as far as possible.
- Do not allow the hip to abduct or rotate.

Hip Abduction VIDEO 4.10

To increase abduction of the hip (stretch the adductors) (Fig. 4.28).

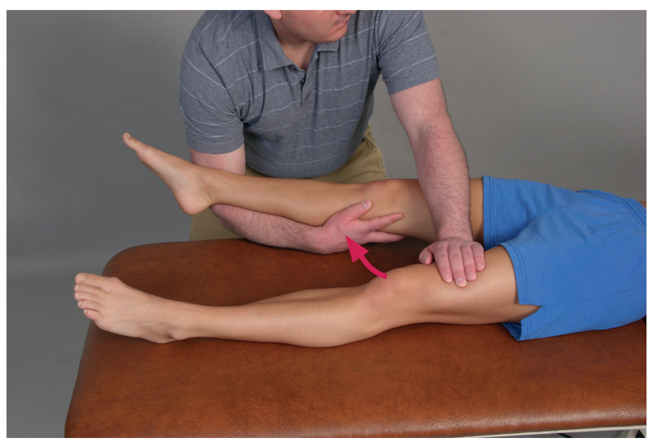

FIGURE 4.28 Hand placement and stabilization of the opposite extremity (or pelvis) for the stretching procedure to increase abduction of the hip.

Hand Placement and Procedure

- Support the distal thigh with your arm and forearm.
- Stabilize the pelvis by placing pressure on the opposite anterior iliac crest or by maintaining the opposite lower extremity in slight abduction.
- Abduct the hip as far as possible to stretch the adductors.

NOTE: You may apply your stretch force cautiously at the medial malleolus only if the knee is stable and pain-free. This creates a great deal of stress to the medial supporting structures of the knee and is generally not recommended by the authors.

Hip Adduction VIDEO 4.11

To increase adduction of the hip (stretch the tensor fasciae latae and iliotibial [IT] band) (Fig. 4.29).

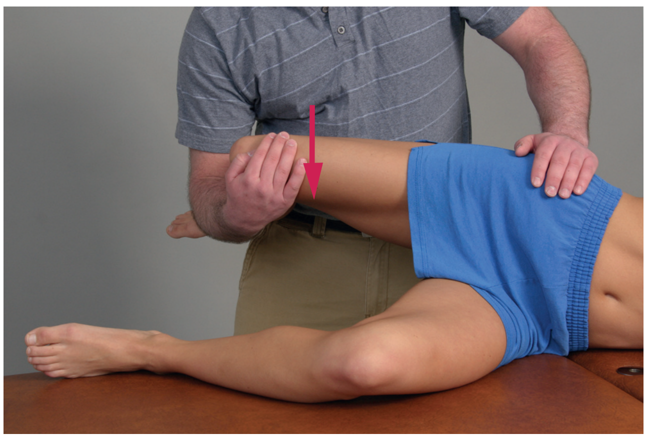

FIGURE 4.29 Patient positioned side-lying. Hand placement and procedure to stretch the tensor fasciae latae and IT band.

Patient Position

Place the patient in a side-lying position with the hip to be stretched uppermost. Flex the bottom hip and knee to stabilize the patient.

Hand Placement and Procedure

- Stabilize the pelvis at the iliac crest with your proximal hand.
- Flex the knee and extend the patient's hip to neutral or into slight hyperextension, if possible.
- Let the patient's hip adduct with gravity and apply an additional stretch force with your other hand to the lateral aspect of the distal femur to further adduct the hip.

NOTE: If the patient's hip cannot be extended to neutral, the hip flexors must be stretched before the tensor fasciae latae can be stretched.

Hip External Rotation

To increase external rotation of the hip (stretch the internal rotators) (Fig. 4.30 A).

Patient Position

Place the patient in a prone position, hips extended and knee flexed to 90°.

FIGURE 4.30 (A) Hand placement and stabilization of the pelvis to increase external rotation of the hip.

Hand Placement and Procedure

- Grasp the distal tibia of the extremity to be stretched.
- Stabilize the pelvis by applying pressure with your other hand across the buttocks.
- Apply pressure to the lateral malleolus or lateral aspect of the tibia, and externally rotate the hip as far as possible.

Alternate Position and Procedure

Sitting at the edge of a table with hips and knees flexed to 90°:

- Stabilize the pelvis by applying pressure to the iliac crest with one hand.
- Apply the stretch force to the lateral malleolus or lateral aspect of the lower leg, and externally rotate the hip.

NOTE: When you apply the stretch force against the lower leg in this manner, thus crossing the knee joint, the knee must be stable and pain-free. If the knee is not stable, it is possible to apply the stretch force by grasping the distal thigh, but the leverage is poor and there is a tendency to twist the skin.

Hip Internal Rotation

To increase internal rotation of the hip (stretch the external rotators) (Fig. 4.30 B).

Patient Position and Stabilization

Position the patient the same as when increasing external rotation, described previously.

Hand Placement and Procedure

Apply pressure to the medial malleolus or medial aspect of the tibia, and internally rotate the hip as far as possible.

FIGURE 4.30—cont'd (B) Hand placement and stabilization of the pelvis to increase internal rotation of the hip with the patient prone.

The Knee: Special Considerations **VIDEO 4.12**

The position of the hip during stretching influences the flexibility of the flexors and extensors of the knee. The flexibility of the hamstrings and the rectus femoris must be examined and evaluated separately from the one-joint muscles that affect knee motion.

Knee Flexion

To increase knee flexion (stretch the knee extensors) (Fig. 4.31).

Patient Position

Have the patient assume a prone position.

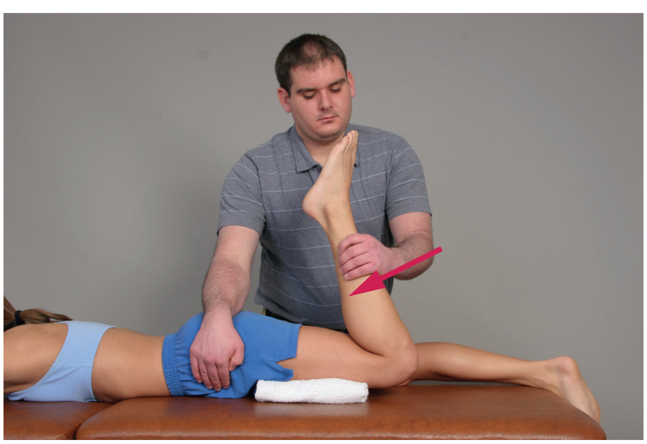

FIGURE 4.31 Hand placement and stabilization to increase knee flexion (stretch the rectus femoris and quadriceps) with the patient lying prone.

Hand Placement and Procedure

- Stabilize the pelvis by applying downward pressure across the buttocks.
- Grasp the anterior aspect of the distal tibia, and flex the patient's knee.

PRECAUTION: Place a rolled towel under the thigh just above the knee to prevent compression of the patella against the table during the stretch. Stretching the knee extensors too vigorously in the prone position can traumatize the knee joint and cause swelling.

Alternate Position and Procedure

- Have the patient sit with the thigh supported on the treatment table and leg flexed over the edge as far as possible.
- Stabilize the anterior aspect of the proximal femur with one hand.
- Apply the stretch force to the anterior aspect of the distal tibia and flex the patient's knee as far as possible.

NOTE: This position is useful when working in the 0° to 100° range of knee flexion. The prone position is best for increasing knee flexion from 90° to 135°.

Knee Extension

To increase knee extension in the midrange (stretch the knee flexors) (Fig. 4.32).

FIGURE 4.32 Hand placement and stabilization to increase midrange knee extension with the patient lying prone.

Patient Position

Place the patient in a prone position and put a small, rolled towel under the patient's distal femur, just above the patella.

Hand Placement and Procedure

- Grasp the distal tibia with one hand and stabilize the buttocks to prevent hip flexion with the other hand.
- Slowly extend the knee to stretch the knee flexors.

End-Range Knee Extension **VIDEO 4.13**

To increase end-range knee extension (Fig. 4.33).

FIGURE 4.33 Hand placement and stabilization to increase terminal knee extension.

Patient Position

Patient assumes a supine position.

Hand Placement and Procedure

- Grasp the distal tibia of the knee to be stretched.
- Stabilize the hip by placing your hand or forearm across the anterior thigh. This prevents hip flexion during stretching.
- Apply the stretch force to the posterior aspect of the distal tibia, and extend the patient's knee.

The Ankle and Foot: Special Considerations

VIDEO 4.14

The ankle and foot are composed of multiple joints. Consider the mobility of these joints (see Chapter 5) as well as the multijoint muscles that cross these joints when increasing ROM of the ankle and foot.

Ankle Dorsiflexion

To increase dorsiflexion of the ankle with the knee extended (stretch the gastrocnemius muscle) (Fig. 4.34).

FIGURE 4.34 Hand placement and procedure to increase dorsiflexion of the ankle with the knee extended (stretching the gastrocnemius).

Hand Placement and Procedure

- Grasp the patient's heel (calcaneus) with one hand, maintain the subtalar joint in a neutral position, and place your forearm along the plantar surface of the foot.
- Stabilize the anterior aspect of the tibia with your other hand.
- Dorsiflex the talocrural joint of the ankle by pulling the calcaneus in an inferior direction with your thumb and fingers while gently applying pressure in a superior direction just proximal to the heads of the metatarsals with your forearm.

To increase dorsiflexion of the ankle with the knee flexed (stretch the soleus muscle). The knee must be flexed to eliminate the effect of the two-joint gastrocnemius muscle. Hand placement, stabilization, and stretch force are the same as when stretching the gastrocnemius.

PRECAUTION: When stretching the gastrocnemius or soleus muscles, avoid placing too much pressure against the heads of the metatarsals and stretching the long arch of the foot. Overstretching the long arch of the foot can cause a flat foot or a rocker-bottom foot.

Ankle Plantarflexion

To increase plantarflexion of the ankle.

Hand Placement and Procedure

- Support the posterior aspect of the distal tibia with one hand.
- Grasp the foot along the tarsal and metatarsal areas.
- Apply the stretch force to the anterior aspect of the foot, and plantarflex the foot as far as possible.

Ankle Inversion and Eversion

To increase inversion and eversion of the ankle. Inversion and eversion of the ankle occur at the subtalar joint as a component of pronation and supination. Mobility of the subtalar joint (with appropriate strength) is particularly important for walking on uneven surfaces.

Hand Placement and Procedure

- Stabilize the talus by grasping just distal to the malleoli with one hand.
- Grasp the calcaneus with your other hand, and move it medially and laterally at the subtalar joint.

Stretching Specific Muscles of the Ankle and Foot

Hand Placement and Procedure

- Stabilize the distal tibia with your proximal hand.
- Grasp around the foot with your other hand and align the motion and force opposite the line of pull of the tendons. Apply the stretch force against the bone to which the muscle attaches distally.
  - *To stretch the tibialis anterior (which inverts and dorsiflexes the ankle):* Grasp the dorsal aspect of the foot

across the tarsals and metatarsals and plantarflex and abduct the foot.

- *To stretch the tibialis posterior (which plantarflexes and inverts the foot):* Grasp the plantar surface of the foot around the tarsals and metatarsals and dorsiflex and abduct the foot.
- *To stretch the peroneals (which evert the foot):* Grasp the lateral aspect of the foot at the tarsals and metatarsals and invert the foot.

Toe Flexion and Extension

To increase flexion and extension of the toes: It is best to stretch any musculature that limits motion in the toes individually. With one hand, stabilize the bone proximal to the restricted joint, and with the other hand, move the phalanx in the desired direction.

Neck and Trunk

Stretching techniques to increase mobility in the cervical, thoracic, and lumbar spine may be found in Chapter 16.

Self-Stretching Techniques

Examples of self-stretching techniques, performed independently by the patient after appropriate instruction, may be found in Chapters 17 through 22 (upper and lower extremities) and Chapter 16 (neck and trunk).

Independent Learning Activities

Critical Thinking and Discussion

1. What physical findings from an examination of a patient would lead you to decide that stretching exercises were an appropriate intervention?
2. Discuss the advantages and disadvantages of various stretching exercises, specifically manual stretching, self-stretching, and mechanical stretching. Under what circumstances would one form be a more appropriate choice than another?
3. Discuss how the effectiveness of a program of stretching activities is influenced by the responses of contractile and noncontractile soft tissues to stretch. Consider such factors as intensity, speed, duration, and frequency of stretch.
4. Discuss how your approach to and application of stretching would differ when developing stretching exercises for a healthy young adult with limited mobility in the (a) shoulder, (b) knee, or (c) ankle in contrast to an elderly individual with osteoporosis and limited motion in the same regions.
5. Explain the procedures for and rationale behind each of the following types of neuromuscular inhibition: HR, HR-AC, CR, and AC. Under what circumstances would you choose one technique over another?
6. Select a popular exercise videotape. Review and critique the flexibility exercises on the tape. Was there a balance in the flexibility exercises in the program? Were the exercises executed safely and correctly? Were the exercises appropriate for the target population?
7. Your patient has been attending Pilates classes over the past few months, but is now receiving your therapy services for management of a chronic strain of the hamstrings. How could you integrate your patient's participation in these classes with your plan of care?

Laboratory Practice

1. Manually stretch as many major muscle groups of the upper and lower extremities as is *safe* and *practical* with the patient in prone-lying, side-lying, or seated positions.
2. While considering individual muscle actions and lines of pull, demonstrate how to specifically and fully elongate the following muscles: pectoralis major, biceps brachii, brachioradialis, brachialis, triceps, extensor or flexor carpi ulnaris or radialis, flexor digitorum superficialis or profundus, rectus femoris versus the iliopsoas, gastrocnemius versus soleus, and the tibialis anterior and posterior.
3. Teach your partner how to stretch major muscle groups of the upper and lower extremities using either body weight or a cuff weight as the stretch force. Be sure to include effective stabilization procedures for these stretching techniques whenever possible.
4. Using either the hold-relax or contract-relax and the hold-relax agonist contraction PNF stretching techniques, elongate at least two major muscle groups at the shoulder, elbow, wrist, hip, knee, and ankle. Be sure to position, align, and stabilize your partner properly.
5. Design an effective and efficient series of self-stretching exercises that a person who works at a desk most of the day could incorporate into a daily home fitness routine. Demonstrate and teach each self-stretching exercise to your laboratory partner.
6. Identify a recreational/sport activity that your partner enjoys (i.e., tennis, golf, cycling, jogging, etc.) and design and demonstrate a program of self-stretching exercises to prepare your partner for the activity and reduce the risk of injury.
7. Design a program of progressive relaxation exercises for total body relaxation. Then, implement the relaxation training sequence with your partner.

CHAPTER

5

Peripheral Joint Mobilization/Manipulation

Joint mobilization, also known as manipulation, refers to manual therapy techniques that are used to modulate pain and treat joint impairments that limit range of motion (ROM) by specifically addressing the altered mechanics of the joint. The altered joint mechanics may be due to pain and muscle guarding, joint effusion, contractures or adhesions in the joint capsules or supporting ligaments, or aberrant joint motion. Joint mobilization stretching techniques differ from other forms of passive or self-stretching (described in Chapter 4) in that they specifically address restricted capsular tissue by replicating normal joint mechanics while minimizing abnormal compressive stresses on the articular cartilage in the joint.[15]

Historically, mobilization has been the preferred term to use as therapists began using the passive, skilled joint

techniques, because mobilization had a less aggressive connotation than manipulation. High-velocity thrust techniques, typically called manipulation, were not universally taught or used by most practitioners. However, with the increased level of education[2a,4] and current practice of physical therapy,[2] both non-thrust and thrust manipulation techniques are skills that therapists are learning and safely using in many practice settings. The *Manipulation Education Manual for Physical Therapist Professional Degree Programs*[2a] as well as the *Guide to Physical Therapist Practice*[2] couple the terms "mobilization" and "manipulation" in order to demonstrate their common usage.

A recent editorial[22a] described problems with using the terms interchangeably. The authors cited confusion in interpreting research and describing outcomes when the techniques used are not clearly defined. They also indicated possible confusion in communicating with patients and with referral sources. It is, therefore, critical that the practitioner clearly understands and defines the characteristics of the techniques used when referring to manipulative techniques.

In this text, the terms "mobilization" and "manipulation" will be used interchangeably, with the distinction made between non-thrust and thrust techniques. The procedures section in this chapter describes documentation and the importance of identifying rate, range, and direction of force application, as well as target, relative structural movement, and patient position whenever referring to mobilization/manipulation intervention techniques.[22] This information should be used in all documentation and communication in order to minimize discrepancies in interpretation of outcomes.

To use joint mobilization/manipulation techniques for effective treatment, the practitioner must know and be able to examine the anatomy, arthrokinematics, and pathology of the neuromusculoskeletal system and to recognize when the techniques are indicated or when other techniques would be more effective for regaining lost motion. Indiscriminate use of joint techniques, when not indicated, could lead to potential harm to the patient's joints. We assume that, prior to learning the techniques presented in this text, the student or therapist has had (or will be concurrently learning) orthopedic examination and evaluation and, therefore, will be able to choose appropriate, safe techniques for treating the patient's impairments. The reader is referred to several resources for additional study of examination and evaluation procedures.[5,11,15,18] When indicated, joint manipulative techniques are safe, effective means of restoring or maintaining joint play and can also be used for treating pain.[15]

Principles of Joint Mobilization/Manipulation

Definitions of Terms

Mobilization/Manipulation

As noted in the introductory paragraphs, mobilization and manipulation are two terms that have come to have the same meaning[2a,19] and are, therefore, interchangeable. In general, they are passive, skilled manual therapy techniques applied to joints and related soft tissues at varying speeds and amplitudes using physiological or accessory motions for therapeutic purposes.[2] The varying speeds and amplitudes can range from a small-amplitude force applied at fast velocity to a large-amplitude force applied at slow velocity—that is, there is a continuum of intensities and speeds at which the technique could be applied.[2]

Thrust manipulation/high-velocity thrust (HVT). Thrust refers to high-velocity, short-amplitude techniques.[11,26] The thrust is performed at the end of the pathological limit of the joint and is intended to alter positional relationships, snap adhesions, or stimulate joint receptors.[26] Pathological limit means the end of the available ROM when there is restriction.

NOTE: The terms thrust and manipulation are often used interchangeably,[4] but with the trend to use manipulation to include all manipulative techniques, including non-thrust techniques, this text will not use these two terms interchangeably.

Self-Mobilization (Auto-Mobilization)

Self-mobilization refers to self-stretching techniques that specifically use joint traction or glides that direct the stretch force to the joint capsule. When indicated, these techniques are described in the chapters on specific regions of the body.

Mobilization with Movement

Mobilization with movement (MWM) is the concurrent application of sustained accessory mobilization applied by a therapist and an active physiological movement to end-range applied by the patient. Passive end-of-range overpressure, or stretching, is then delivered without pain as a barrier. The techniques are always applied in a pain-free direction and are described as correcting joint tracking from a positional fault.[21,23] Brian Mulligan of New Zealand originally described these techniques.[23] MWM techniques related to specific peripheral joint regions are described in Chapters 17 through 22.

Physiological Movements

Physiological movements are movements the patient can do voluntarily (e.g., the classic or traditional movements, such as flexion, abduction, and rotation). The term *osteokinematics* is used when these motions of the bones are described.

Accessory Movements

Accessory movements are movements in the joint and surrounding tissues that are necessary for normal ROM but that cannot be actively performed by the patient.[24] Terms that relate to accessory movements are *component motions* and *joint play*.

Component motions. These are motions that accompany active motion but are not under voluntary control. The term is often used synonymously with accessory movement. For

example, motions such as upward rotation of the scapula and rotation of the clavicle, which occur with shoulder flexion, and rotation of the fibula, which occurs with ankle motions, are component motions.

Joint play. Joint play describes the motions that occur between the joint surfaces and also the distensibility or "give" in the joint capsule, which allows the bones to move. The movements are necessary for normal joint functioning through the ROM and can be demonstrated passively, but they cannot be performed actively by the patient.[26] The movements include distraction, sliding, compression, rolling, and spinning of the joint surfaces. The term *arthrokinematics* is used when these motions of the bone surfaces within the joint are described.

NOTE: Procedures to distract or slide the joint surfaces to decrease pain or restore joint play are the fundamental joint mobilization techniques described in this text.

Manipulation Under Anesthesia

Manipulation under anesthesia is a procedure used to restore full ROM by breaking adhesions around a joint while the patient is anesthetized. The technique may be a rapid thrust or a passive stretch using physiological or accessory movements. Therapists may assist surgeons in the application of these skilled techniques in the operating room and continue with follow-up care.

Muscle Energy

Muscle energy techniques use active contraction of deep muscles that attach near the joint and whose line of pull can cause the desired accessory motion. The technique requires the therapist to provide stabilization to the segment on which the distal aspect of the muscle attaches. A command for an isometric contraction of the muscle is given that causes accessory movement of the joint. Several specific muscle energy techniques are described for the subcranial region of the cervical spine in Chapter 16.

Basic Concepts of Joint Motion: Arthrokinematics

Joint Shapes

The type of motion occurring between bony partners in a joint is influenced by the shape of the joint surfaces. The shape may be described as *ovoid* or *sellar*.[15,17,29]

- In ovoid joints one surface is convex, and the other is concave (Fig. 5.1 A).
- In sellar (saddle) joints, one surface is concave in one direction and convex in the other, with the opposing surface convex and concave, respectively—similar to a horseback rider being in complementary opposition to the shape of a saddle (Fig. 5.1 B).

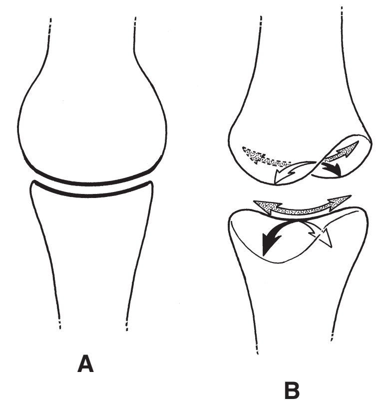

FIGURE 5.1 (A) With ovoid joints, one surface is convex, and the other is concave. **(B)** With saddle (sellar) joints, one surface is concave in one direction and convex in the other, with the opposing surface convex and concave, respectively.

Types of Motion

As a bony lever moves about an axis of motion, there is also movement of the bone surface on the opposing bone surface in the joint.

- The movement of the bony lever is called *swing* and is classically described as flexion, extension, abduction, adduction, and rotation. The amount of movement can be measured in degrees with a goniometer and is called ROM.
- Motion of the bone surfaces in the joint is a variable combination of *rolling* and *sliding*, or *spinning*.[15,17,29] These accessory motions allow greater angulation of the bone as it swings. For the rolling, sliding, or spinning to occur, there must be adequate capsule laxity or joint play.

Roll

Characteristics of one bone rolling on another (Fig. 5.2) are as follows.

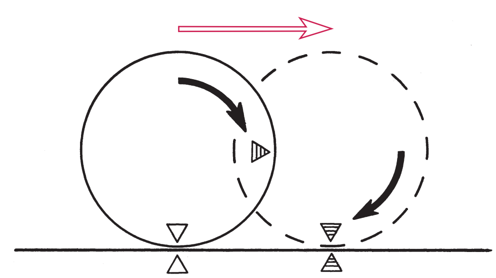

FIGURE 5.2 Representation of one surface rolling on another. New points on one surface meet new points on the opposing surface.

- The surfaces are incongruent.
- New points on one surface meet new points on the opposing surface.
- Rolling results in angular motion of the bone (swing).
- Rolling is always in the same direction as the swinging bone motion whether the surface is convex (Fig. 5.3 A) or concave (Fig. 5.3 B).

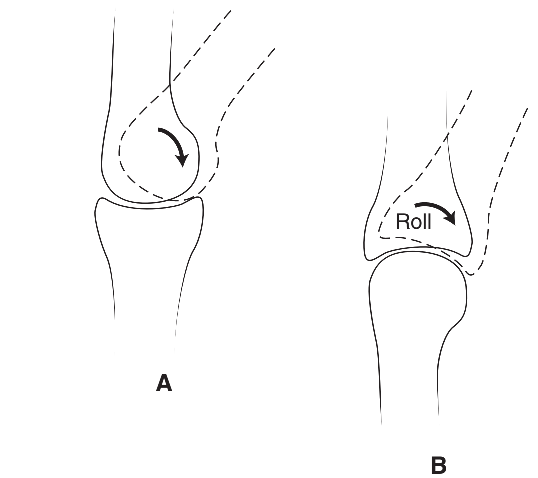

FIGURE 5.3 Rolling is always in the same direction as bone motion, whether the moving bone is **(A)** convex or **(B)** concave.

- Rolling, if it occurs alone, causes compression of the surfaces on the side to which the bone is swinging and separation on the other side. Passive stretching using bone angulation alone may cause stressful compressive forces to portions of the joint surface, potentially leading to joint damage.
- In normally functioning joints, pure rolling does not occur alone but in combination with joint sliding and spinning.

Slide/Translation

Characteristics of one bone sliding (translating) across another include the following.

- For a pure slide, the surfaces must be congruent, either flat (Fig. 5.4 A) or curved (Fig. 5.4 B).

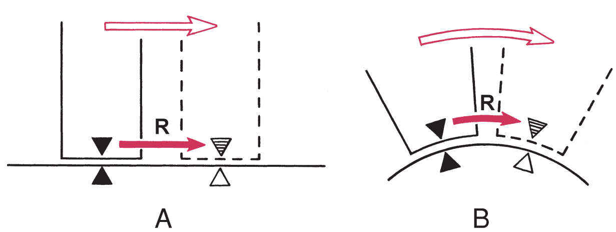

FIGURE 5.4 Representation of one surface sliding on another, whether **(A)** flat or **(B)** curved. The same point on one surface comes into contact with new points on the opposing surface.

- The same point on one surface comes into contact with the new points on the opposing surface.
- Pure sliding does not occur in joints, because the surfaces are not completely congruent.
- The direction in which sliding occurs depends on whether the moving surface is concave or convex. Sliding is in the opposite direction of the angular movement of the bone if the moving joint surface is convex (Fig. 5.5 A). Sliding is in the same direction as the angular movement of the bone if the moving surface is concave (Fig. 5.5 B).

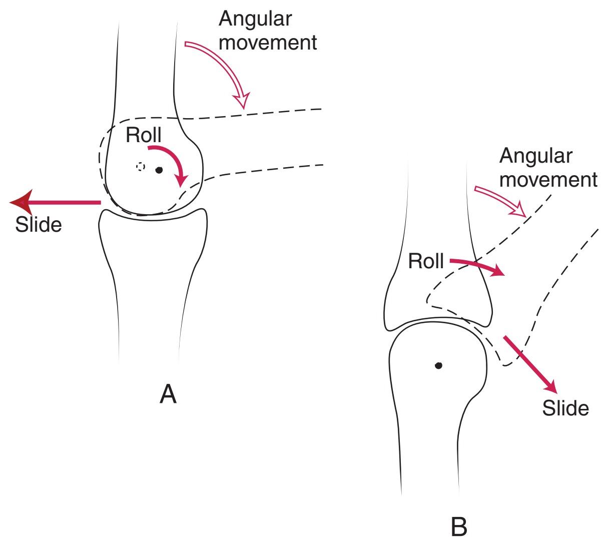

FIGURE 5.5 Representation of the concave-convex rule. **(A)** If the surface of the moving bone is convex, sliding is in the direction opposite to that of the angular movement of the bone. **(B)** If the surface of the moving bone is concave, sliding is in the same direction as the angular movement of the bone.

NOTE: This mechanical relationship is known as the *convex-concave rule* and is the theoretical basis for determining the direction of the mobilizing force when joint gliding techniques are used.[15]

FOCUS ON EVIDENCE

Several studies[10,12,14] have examined the translational movement of the humeral head with shoulder motions and have documented translations opposite to what is predicted by the convex-concave rule. Hsu and associates[13] proposed that this apparent contradiction to the convex-concave rule is the result of asymmetrical tightening of the shoulder joint capsule during movement resulting in translation of the moving bone opposite to the direction of capsular tightening. They documented that stretching the tight capsule with translations that affect the restricting tissues leads to greater ROM in cadaver shoulder joints.

Combined Roll-Sliding in a Joint

- The more congruent the joint surfaces are, the more sliding there is of one bony partner on the other with movement.
- The more incongruent the joint surfaces are, the more rolling there is of one bony partner on the other with movement.
- When muscles actively contract to move a bone, some of the muscles may cause or control the sliding movement of the joint surfaces. For example, the caudal sliding motion of the humeral head during shoulder abduction is caused by the rotator cuff muscles, and the posterior sliding of the tibia during knee flexion is caused by the hamstring muscles. If this function is lost, the resulting abnormal joint mechanics may cause microtrauma and joint dysfunction.

■ The joint mobilization techniques described in this chapter use the sliding component of joint motion to restore joint play and reverse joint hypomobility. Rolling (passive angular stretching) is not used to stretch tight joint capsules, because it causes joint compression.

CLINICAL TIP

When the therapist passively moves the articulating surface using the slide component of joint motion, the technique is called translatoric glide, translation, or simply glide.[15] It is used to control pain when applied gently or to stretch the capsule when applied with a stretch force.

Spin

Characteristics of one bone spinning on another include the following.

■ There is rotation of a segment about a stationary mechanical axis (Fig. 5.6).

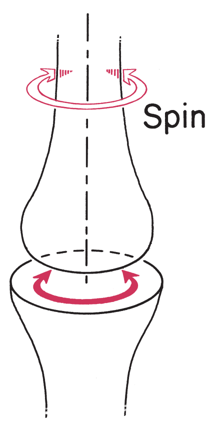

FIGURE 5.6 Representation of spinning. There is rotation of a segment about a stationary mechanical axis.

■ The same point on the moving surface creates an arc of a circle as the bone spins.
■ Spinning rarely occurs alone in joints but in combination with rolling and sliding.
■ Three examples of spin occurring in joints of the body are the shoulder with flexion/extension, the hip with flexion/extension, and the radiohumeral joint with pronation/supination (Fig. 5.7).

Passive-Angular Stretching Versus Joint-Glide Stretching

■ Passive-angular stretching procedures, as when the bony lever is used to stretch a tight joint capsule, may cause increased pain or joint trauma because:
  - The use of a lever magnifies the force at the joint.
  - The force causes compression of the joint surfaces in the direction of the rolling bone (see Fig. 5.3).

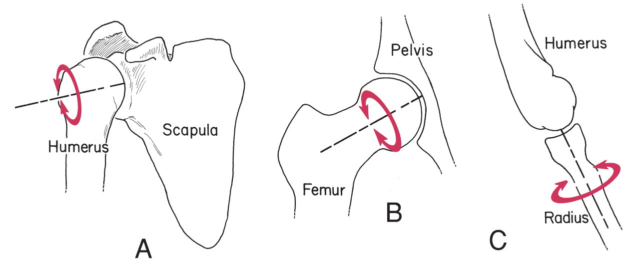

FIGURE 5.7 Examples of joint spin locations in the body. **(A)** Humerus with flexion/extension. **(B)** Femur with flexion/extension. **(C)** Head of the radius with pronation/supination.

  - The roll without a slide does not replicate normal joint mechanics.

■ Joint glide stretching procedures, as when the translatoric slide component of the joint function is used to stretch a tight capsule, are safer and more selective because:
  - The force is applied close to the joint surface and controlled at an intensity compatible with the pathology.
  - The direction of the force replicates the sliding component of the joint mechanics and does not compress the cartilage.
  - The amplitude of the motion is small yet specific to the restricted or adherent portion of the capsule or ligaments. Thus, the forces are selectively applied to the desired tissue.

Other Accessory Motions that Affect the Joint

Compression

Compression is the decrease in the joint space between bony partners.

■ Compression normally occurs in the extremity and spinal joints when weight bearing.
■ Some compression occurs as muscles contract, which provides stability to the joints.
■ As one bone rolls on the other (see Fig. 5.3), some compression also occurs on the side to which the bone is angulating.
■ Normal intermittent compressive loads help move synovial fluid and, thus, help maintain cartilage health.
■ Abnormally high compression loads may lead to articular cartilage changes and deterioration.[17]

Traction/Distraction VIDEO 5.1

Traction and distraction are not synonymous. Traction is a longitudinal pull. Distraction is a separation, or pulling apart.

■ Separation of the joint surfaces (distraction) does not always occur when a traction force is applied to the long axis of a bone. For example, if traction is applied to the shaft of the humerus when the arm is at the side, it results in a glide of the joint surface (Fig. 5.8 A). Distraction of the glenohumeral joint requires a force to be applied at right angles to the glenoid fossa (Fig. 5.8 B).

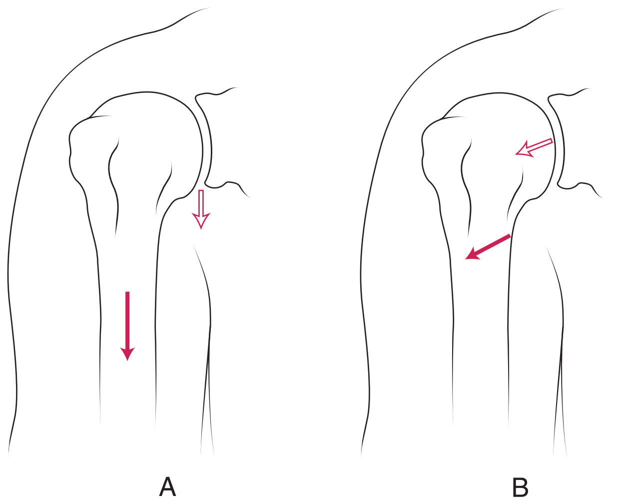

FIGURE 5.8 (A) Traction applied to the shaft of the humerus results in caudal gliding of the joint surface. **(B)** Distraction of the glenohumeral joint requires separation at right angles to the glenoid fossa.

- For clarity, whenever there is pulling on the long axis of a bone, the term *long-axis traction* is used. Whenever the surfaces are to be separated, the term *distraction, joint traction,* or *joint separation* is used.

CLINICAL TIP

For joint mobilization/manipulation techniques, distraction is used to control or relieve pain when applied gently or to stretch the capsule when applied with a stretch force. A slight distraction force is used when applying gliding techniques.

Effects of Joint Motion

Joint motion stimulates biological activity by moving synovial fluid, which brings nutrients to the avascular articular cartilage of the joint surfaces and intra-articular fibrocartilage of the menisci.[17] Atrophy of the articular cartilage begins soon after immobilization is imposed on joints.[1,7,8]

Extensibility and tensile strength of the articular and periarticular tissues are maintained with joint motion. With immobilization there is fibrofatty proliferation, which causes intra-articular adhesions as well as biochemical changes in tendon, ligament, and joint capsule tissue, which in turn causes joint contractures and ligamentous weakening.[1]

Afferent nerve impulses from joint receptors transmit information to the central nervous system and, therefore, provide awareness of position and motion. With injury or joint degeneration, there is a potential decrease in an important source of proprioceptive feedback that may affect an individual's balance response.[30] Joint motion provides sensory input relative to[32,33]:

- Static position and sense of speed of movement (type I receptors found in the superficial joint capsule).
- Change of speed of movement (type II receptors found in deep layers of the joint capsule and articular fat pads).
- Sense of direction of movement (type I and III receptors; type III found in joint ligaments).
- Regulation of muscle tone (type I, II, and III receptors).
- Nociceptive stimuli (type IV receptors found in the fibrous capsule, ligaments, articular fat pads, periosteum, and walls of blood vessels).

Indications and Limitations for Use of Joint Mobilization/ Manipulation

Gentle mobilizations may be used to treat pain and muscle guarding, whereas stretching techniques are used to treat restricted movement.

Pain, Muscle Guarding, and Spasm

Painful joints, reflex muscle guarding, and muscle spasm can be treated with *gentle joint-play* techniques to stimulate neurophysiological and mechanical effects.[11]

Neurophysiological Effects

Small-amplitude oscillatory and distraction movements are used to stimulate the mechanoreceptors that may inhibit the transmission of nociceptive stimuli at the spinal cord or brain stem levels.[26,29]

Mechanical Effects

Small-amplitude distraction or gliding movements of the joint are used to cause synovial fluid motion, which is the vehicle for bringing nutrients to the avascular portions of the articular cartilage (and intra-articular fibrocartilage when present). Gentle joint-play techniques help maintain nutrient exchange and, thus, prevent the painful and degenerating effects of stasis when a joint is swollen or painful and cannot move through the ROM. When applied to treat pain, muscle guarding, or muscle spasm, these techniques should not place stretch on the reactive tissues (see section on Contraindications and Precautions).

Reversible Joint Hypomobility

Reversible joint hypomobility can be treated with *progressively vigorous joint-play stretching* techniques to elongate hypomobile capsular and ligamentous connective tissue. Sustained or oscillatory stretch forces are used to distend the shortened tissue mechanically.[11,15]

Positional Faults/Subluxations

A faulty position of one bony partner with respect to its opposing surface may result in limited motion or pain. This can occur with a traumatic injury, after periods of immobility, or with muscle imbalances. The faulty positioning may be perpetuated with maladapted neuromuscular control across

the joint, so whenever attempting active ROM, there is faulty tracking of the joint surfaces resulting in pain or limited motion. MWM techniques attempt to realign the bony partners while the person actively moves the joint through its ROM.[23] Thrust techniques are used to reposition an obvious subluxation, such as a pulled elbow or capitate-lunate subluxation.

Progressive Limitation

Diseases that progressively limit movement can be treated with joint-play techniques to maintain available motion or retard progressive mechanical restrictions. The dosage of distraction or glide is dictated by the patient's response to treatment and the state of the disease.

Functional Immobility

When a patient cannot functionally move a joint for a period of time, the joint can be treated with nonstretch gliding or distraction techniques to maintain available joint play and prevent the degenerating and restricting effects of immobility.

FOCUS ON EVIDENCE

DiFabio[6] summarized evidence on the effectiveness of manual therapy (primarily mobilization/manipulation) for patients with somatic pain syndromes in the low back region and concluded that there was significantly greater improvement in patients receiving manual therapy than in controls. Boissonnault and associates[4] cited several studies that demonstrated the effectiveness of manual therapy interventions (defined as "a continuum of skilled passive movements to the joints and/or related soft tissues that are applied at varying speeds and amplitudes") in patients with low back pain as well as shoulder impingement, knee osteoarthritis, and cervical pain. However, there is a lack of randomized, controlled studies on the effects of mobilization for all the peripheral joints. Case studies that describe patient selection and/or interventions using joint mobilization/manipulation techniques are identified in various chapters in this text (see Chapters 15 and 17 to 22).

Limitations of Joint Mobilization/ Manipulation Techniques

Joint techniques cannot change the disease process of disorders such as rheumatoid arthritis or the inflammatory process of injury. In these cases, treatment is directed toward minimizing pain, maintaining available joint play, and reducing the effects of any mechanical limitations (see Chapter 11).

The skill of the therapist affects the outcome. The techniques described in this text are relatively safe if directions are followed and precautions are heeded. However, if these techniques are used indiscriminately on patients not properly examined and screened for such maneuvers or if they are applied too vigorously for the condition, joint trauma or hypermobility may result.

Contraindications and Precautions

The only true contraindications to mobilization/manipulation stretching techniques are hypermobility, joint effusion, and inflammation.

Hypermobility

- The joints of patients with potential necrosis of the ligaments or capsule should not be mobilized with stretching techniques.
- Patients with painful hypermobile joints may benefit from gentle joint-play techniques if kept within the limits of motion. Stretching is not done.

Joint Effusion

There may be joint swelling (effusion) due to trauma or disease. Rapid swelling of a joint usually indicates bleeding in the joint and may occur with trauma or diseases such as hemophilia. Medical intervention is required for aspiration of the blood to minimize its necrotizing effect on the articular cartilage. Slow swelling (more than 4 hours) usually indicates serous effusion (a buildup of excess synovial fluid) or edema in the joint due to mild trauma, irritation, or a disease such as arthritis.

- Do not stretch a swollen joint with mobilization or passive stretching techniques. The capsule is already on a stretch by being distended to accommodate the extra fluid. The limited motion is from the extra fluid and muscle response to pain, not from shortened fibers.
- Gentle oscillating motions that do not stress or stretch the capsule may help block the transmission of a pain stimulus so it is not perceived and also may help improve fluid flow while maintaining available joint play.
- If the patient's response to gentle techniques results in increased pain or joint irritability, the techniques were applied too vigorously or should not have been done with the current state of pathology.

Inflammation

Whenever inflammation is present, stretching increases pain and muscle guarding and results in greater tissue damage. Gentle oscillating or distraction motions may temporarily inhibit the pain response. See Chapter 10 for an appropriate approach to treatment when inflammation is present.

Conditions Requiring Special Precautions for Stretching

In most cases, joint mobilization techniques are safer than passive angular stretching, in which the bony lever is used to stretch tight tissue and joint compression results. Mobilization

may be used with *extreme care* in the following conditions if the signs and the patient's response are favorable.

- Malignancy.
- Bone disease detectable on radiographs.
- Unhealed fracture. (The site of the fracture and the stabilization provided will dictate whether or not manipulative techniques can be safely applied.)
- Excessive pain. (Determine the cause of pain and modify treatment accordingly.)
- Hypermobility in associated joints. (Associated joints must be properly stabilized so the mobilization force is not transmitted to them.)
- Total joint replacements. (The mechanism of the replacement is self-limiting, and, therefore, the mobilization techniques may be inappropriate.)
- Newly formed or weakened connective tissue such as immediately after injury, surgery, or disuse or when the patient is taking certain medications such as corticosteroids. (Gentle progressive techniques within the tolerance of the tissue help align the developing fibrils, but forceful techniques are destructive.)
- Systemic connective tissue diseases such as rheumatoid arthritis, in which the disease weakens the connective tissue. (Gentle techniques may benefit restricted tissue, but forceful techniques may rupture tissue and result in instabilities.)
- Elderly individuals with weakened connective tissue and diminished circulation. (Gentle techniques within the tolerance of the tissue may be beneficial to increase mobility.)

Procedures for Applying Passive Joint Techniques

Examination and Evaluation

If the patient has limited or painful motion, examine and decide which tissues are limiting function and the state of pathology. Determine whether treatment should be directed primarily toward relieving pain or stretching a joint or soft tissue limitation.[5,11]

Quality of pain

The quality of pain when testing the ROM helps determine the stage of recovery and the dosage of techniques used for treatment (see Fig. 10.2).

- If pain is experienced *before* tissue limitation—such as the pain that occurs with muscle guarding after an acute injury or during the active stage of a disease—gentle pain-inhibiting joint techniques may be used. The same techniques also can help maintain joint play (see next section, 'Grades or Dosages of Movement'). Stretching under these circumstances is contraindicated.
- If pain is experienced *concurrently* with tissue limitation—such as the pain and limitation that occur when damaged tissue begins to heal—the limitation is treated cautiously. Gentle stretching techniques specific to the tight structure are used to improve movement gradually yet not exacerbate the pain by reinjuring the tissue.
- If pain is experienced *after* tissue limitation is met because of stretching of tight capsular or periarticular tissue, the stiff joint can be aggressively stretched with joint-play techniques and the periarticular tissue with the stretching techniques described in Chapter 4.

Capsular Restriction

The joint capsule is limiting motion and should respond to mobilization techniques if some or all of the following signs are present.

- The passive ROM for that joint is limited in a capsular pattern. (These patterns are described for each peripheral joint under the respective sections on joint problems in Chapters 17 through 22).
- There is a firm capsular end-feel when overpressure is applied to the tissues limiting the range.
- There is decreased joint-play movement when mobility tests (articulations) are performed.
- An adhered or contracted ligament is limiting motion if there is decreased joint play and pain when the fibers of the ligament are stressed; ligaments often respond to joint mobilization techniques if applied specific to their line of stress.

Subluxation or Dislocation

Subluxation or dislocation of one bony part on another and loose intra-articular structures that block normal motion may respond to thrust techniques. Some of the simpler thrust techniques for extremity joints are described in the respective chapters in this text; thrust techniques for the spine are described in Chapter 16.

Documentation

Use of standardized terminology for communication is recommended in order to facilitate research on effective outcomes using mobilization/manipulation. A task force formed by the American Academy of Orthopaedic Manual Physical Therapists (AAOMPT) published recommendations regarding the characteristics to use in the description of manipulative techniques.[22] These are listed in Box 5.1.

The principles describing the *rate of application of the force, location in range of available movement,* and *direction and target of force* that the therapist applies are described in this section. The actual *target of force, structural movement,* and *patient position* are specific to each joint technique; these are described in the section on peripheral joint mobilization techniques in this chapter, for the temporomandibular joint in Chapter 15, and for the spine in Chapter 16.

Grades or Dosages of Movement for Non-Thrust and Thrust Techniques

Two systems of grading dosages (or rate of application) and their application in the range of available motion have been popularized.[11,15]

BOX 5.1 Characteristics to Describe Mobilization and Manipulation Techniques[22]

1. *Rate of application of the force*
2. *Location in range of available movement*
3. *Direction of force as applied by the therapist*
4. *Target of force* (The specific structure to which the force is applied is described identifying palpable anatomical structures.)
5. *Relative structural movement* (The structure that is to move is identified first followed by the structure that is kept stable.)
6. *Patient position*

Non-Thrust Oscillation Techniques (Fig. 5.9)

The oscillations may be performed using physiological (osteokinematic) motions or joint-play (arthrokinematic) techniques.

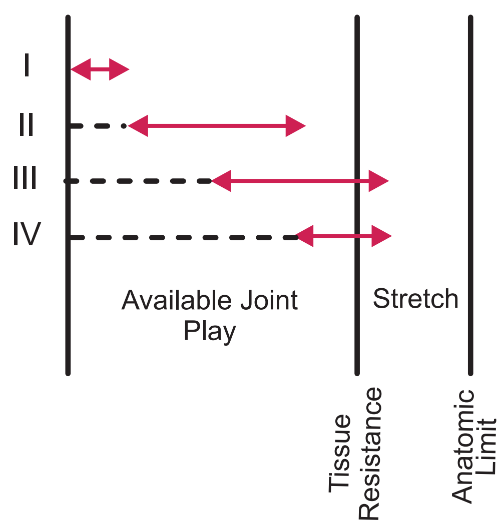

FIGURE 5.9 Representation of oscillation techniques. *(Adapted from Maitland.[11])*

Dosage and Rate of Application

Grade I. Small-amplitude rhythmic oscillations are performed at the beginning of the range. They are usually rapid oscillations, like manual vibrations.

Grade II. Large-amplitude rhythmic oscillations are performed within the range, not reaching the limit. They are usually performed at 2 or 3 per second for 1 to 2 minutes.

Grade III. Large-amplitude rhythmic oscillations are performed up to the limit of the available motion and are stressed into the tissue resistance. They are usually performed at 2 or 3 per second for 1 to 2 minutes.

Grade IV. Small-amplitude rhythmic oscillations are performed at the limit of the available motion and stressed into the tissue resistance. They are usually rapid oscillations, like manual vibrations.

Indications

- Grades I and II are primarily used for treating joints limited by pain or muscle guarding. The oscillations may have an inhibitory effect on the perception of painful stimuli by repetitively stimulating mechanoreceptors that block nociceptive pathways at the spinal cord or brain stem levels.[26,34] These nonstretch motions help move synovial fluid to improve nutrition to the cartilage.
- Grades III and IV are primarily used as stretching maneuvers.
- Vary the speed of oscillations for different effects, such as low amplitude and high speed, to inhibit pain or slow speed to relax muscle guarding.

Non-Thrust Sustained Joint-Play Techniques (Fig. 5.10)

This grading system describes only joint-play techniques that separate (distract) or glide/translate (slide) the joint surfaces.

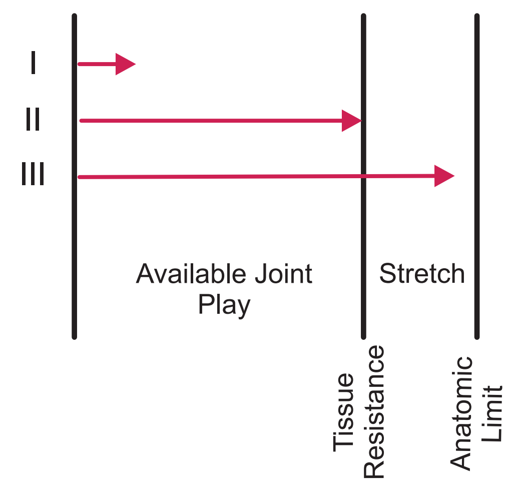

FIGURE 5.10 Representation of sustained joint-play techniques. *(Adapted from Kaltenborn.[15])*

Dosages and Rate of Application

As indicated by the name, rate of application is slow and sustained for several seconds followed by partial relaxation and then repeated depending on the indications.

Grade I (loosen). Small-amplitude distraction is applied when no stress is placed on the capsule. It equalizes cohesive forces, muscle tension, and atmospheric pressure acting on the joint.

Grade II (tighten). Enough distraction or glide is applied to tighten the tissues around the joint. Kaltenborn[15] called this "taking up the slack."

Grade III (stretch). A distraction or glide is applied with an amplitude large enough to place stretch on the joint capsule and surrounding periarticular structures.

Indications

- Grade I distraction is used with all gliding motions and may be used for relief of pain. Apply intermittent distraction for 7 to 10 seconds with a few seconds of rest in between for several cycles. Note the response and either repeat or discontinue.
- Grade II distraction is used for the initial treatment to determine the sensitivity of the joint. Once the joint reaction is known, the treatment dosage is increased or decreased accordingly.
- Gentle grade II distraction applied intermittently may be used to inhibit pain. Grade II glides may be used to maintain joint play when ROM is not allowed.
- Grade III distractions or glides are used to stretch the joint structures and thus increase joint play. For restricted joints, apply a minimum of a 6-second stretch force followed by partial release (to grade I or II), then repeat with slow, intermittent stretches at 3- to 4-second intervals.

Comparison of Oscillation and Sustained Techniques

When using either grading system, dosages I and II are low-intensity and so do not cause a stretch force on the joint capsule or surrounding tissue, although by definition, sustained grade II techniques take up the slack of the tissues, whereas grade II oscillation techniques stay within the slack. Grades III and IV oscillations and grade III sustained stretch techniques are similar in intensity in that they all are applied with a stretch force at the limit of motion. The differences are related to the rhythm or speed of repetition of the stretch force.

- For clarity and consistency, when referring to dosages in this text, the notation *graded oscillations* means to use the dosages as described in the section on oscillation techniques. The notation *sustained grade* means to use the dosages as described in the section on sustained joint-play techniques.
- The choice of using oscillating or sustained techniques depends on the patient's response.
  - When dealing with managing pain, either grade I or II oscillation techniques or slow intermittent grade I or II sustained joint distraction techniques are recommended; the patient's response dictates the intensity and frequency of the joint-play technique.
  - When dealing with loss of joint play and thus decreased functional range, sustained techniques applied in a cyclic manner are recommended; the longer the stretch force can be maintained, the greater the creep and plastic deformation of the connective tissue.
  - When attempting to maintain available range by using joint-play techniques, either grade II oscillating or sustained grade II techniques can be used.

Thrust Manipulation/High Velocity Thrust (HVT)

HVT is a small-amplitude, high-velocity technique.

Application

- Prior to application, the joint is moved to the limit of the motion so that all slack is taken out of the tissue, then a quick thrust is applied to the restricting tissue. It is important to keep the amplitude of the thrust small so as not to damage unrelated tissues or lose control of the maneuver.
- HVT is applied with one repetition only.

Indications

HVT is used to snap adhesions or is applied to a dislocated structure to reposition the joint surfaces.

Positioning and Stabilization

- The patient and the extremity to be treated should be positioned so the patient can relax. To relax the muscles crossing the joint, techniques of inhibition (see Chapter 4) may be used prior to or between mobilization techniques.
- Examination of joint play and the first treatment are initially performed in the resting position for that joint, so the greatest capsule laxity is possible. In some cases, the position to use is the one in which the joint is least painful.
- With progression of treatment, the joint is positioned at or near the end of the available range prior to application of the mobilization force. This places the restricting tissue in its most lengthened position where the stretch force can be more specific and effective.[15]
- Firmly and comfortably stabilize one joint partner, usually the proximal bone. A belt, one of the therapist's hands, or an assistant holding the part may provide stabilization. Appropriate stabilization prevents unwanted stress to surrounding tissues and joints and makes the stretch force more specific and effective.

Direction and Target of Treatment Force

- The treatment force (either gentle or strong) is applied as close to the opposing joint surface as possible. It is imperative that the therapist be able to identify anatomical landmarks and use these as guides for accurate hand placement and force application. The larger the contact surface, the more comfortable the patient will be with the procedure. For example, instead of forcing with your thumb, use the flat surface of your hand.
- The direction of movement during treatment is either parallel or perpendicular to the treatment plane. *Treatment plane* was described by Kaltenborn[15] as a plane perpendicular to a line running from the axis of rotation to the middle of the concave articular surface. The plane is in the concave partner, so its position is determined by the position of the concave bone (Fig. 5.11).
- Distraction techniques are applied perpendicular to the treatment plane. The entire bone is moved so the joint surfaces are separated.
- *Gliding techniques are applied parallel to the treatment plane.* The direction of gliding may be determined by using the

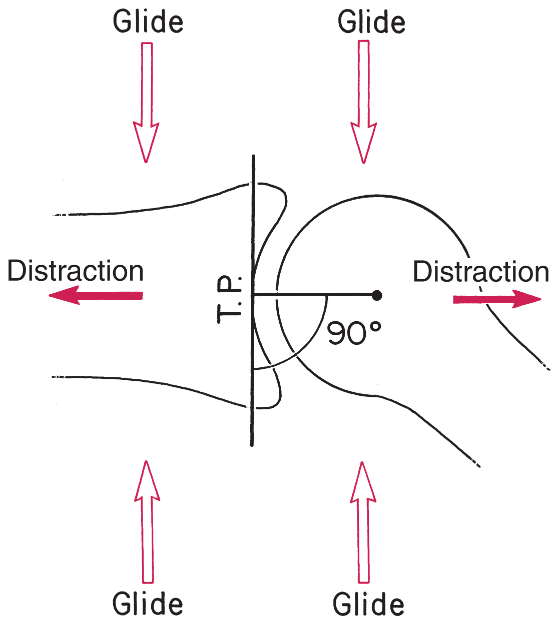

FIGURE 5.11 Treatment plane (T.P.) is at right angles to a line drawn from the axis of rotation to the center of the concave articulating surface and lies in the concave surface. Joint traction (distraction) is applied perpendicular to and glides parallel to the T.P.

convex-concave rule (described earlier in the chapter). If the surface of the moving bony partner is convex, the treatment glide should be opposite to the direction in which the bone swings. If the surface of the moving bony partner is concave, the treatment glide should be in the same direction (see Fig. 5.5).

- The entire bone is moved so there is gliding of one joint surface on the other. The bone should not be used as a lever; it should have no arcing motion (swing), which would cause rolling and thus compression of the joint surfaces.

Initiation and Progression of Treatment (Fig. 5.12)

1. The initial treatment is the same whether treating to decrease pain or increase joint play. The purpose is to determine joint reactivity before proceeding. Use a sustained grade II distraction of the joint surfaces with the joint held in resting position or the position of greatest relaxation.[15] Note the immediate joint response relative to irritability and range.
2. The next day, evaluate joint response or have the patient report the response at the next visit.
   - If there is increased pain and sensitivity, reduce the amplitude of treatment to grade I oscillations.
   - If the joint is the same or better, perform either of the following: Repeat the same maneuver if the goal of treatment is to maintain joint play, or progress the maneuver to stretching techniques if the goal of treatment is to increase joint play.
3. To maintain joint play by using gliding techniques when ROM techniques are contraindicated or not possible for a period of time, use sustained grade II or grade II oscillation techniques.
4. To progress the stretch technique, move the bone to the end of the available ROM[15], then apply a sustained grade III distraction or glide technique. Progressions include prepositioning the bone at the end of the available range and rotating it prior to applying grade III distraction or glide techniques. The direction of the glide and rotation

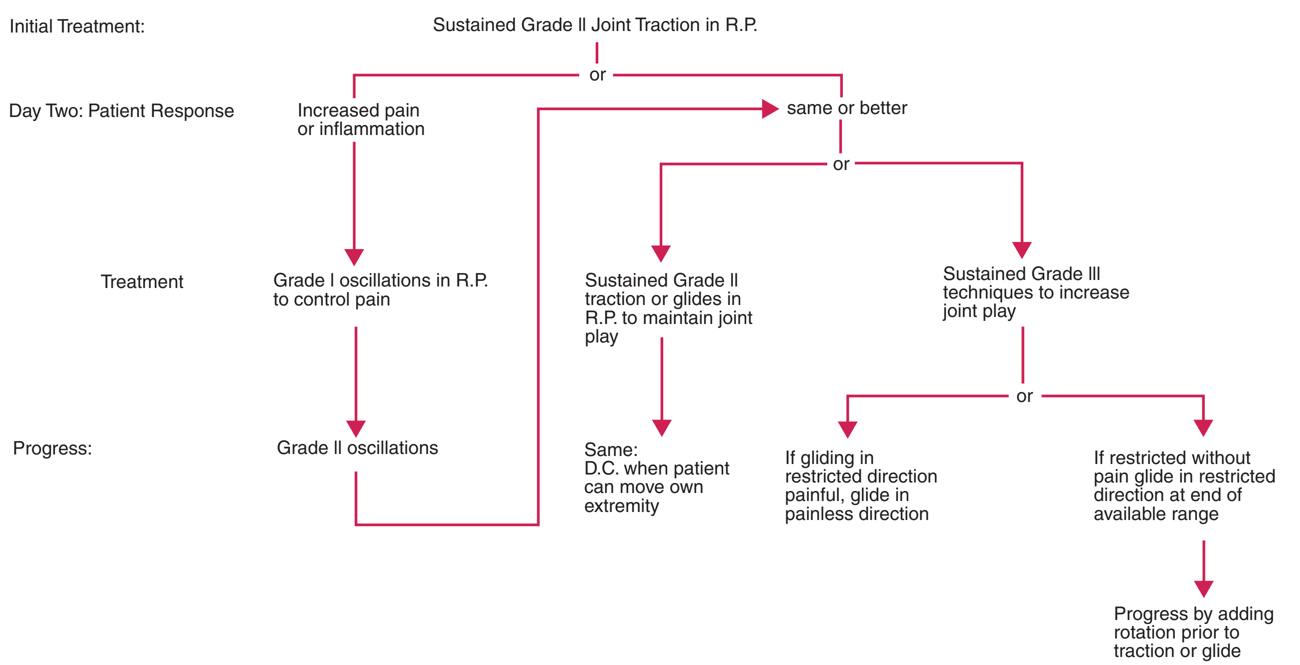

FIGURE 5.12 Initiation and progression of treatment.

is dictated by the joint mechanics. For example, laterally rotate the humerus as shoulder abduction is progressed; medially rotate the tibia as knee flexion is progressed.

CLINICAL TIP

For effective mobilization:

- Warm the tissue around the joint prior to stretching. Modalities, massage, or gentle muscle contractions increase the circulation and warm the tissues.
- Muscle relaxation techniques and grade I and II oscillation techniques may inhibit muscle guarding and should be alternated with sustained stretching techniques, if necessary.
- When using grade III gliding techniques, a grade I distraction should be used with it. A grade II or III distraction should not be used with a grade III glide to avoid excessive trauma to the joint.
- If gliding in the restricted direction is too painful, begin gliding mobilizations in the painless direction. Progress to gliding in the restricted direction when mobility improves and pain decreases.
- When applying the stretching techniques, move the bony partner through the available range of joint play first—that is, "take up the slack." When tissue resistance is felt, apply the stretch force against the restriction.
- Incorporate MWM techniques (described in the following section) as part of the total approach to treatment.

Patient Response

- Stretching maneuvers usually cause soreness. Perform the maneuvers on alternate days to allow the soreness to decrease and tissue healing to occur between stretching sessions. The patient should perform ROM into any newly gained range during this time.
- If there is increased pain lasting longer than 24 hours after stretching, the dosage (amplitude) or duration of treatment was too vigorous. Decrease the dosage or duration until the pain is under control.
- The patient's joint and ROM should be reassessed after treatment and again before the next treatment. Alterations in treatment are dictated by the joint response.

Total Program

Mobilization techniques are one part of a total treatment program when there is decreased function. If muscles or connective tissues are also limiting motion, PNF stretching and passive stretching techniques are alternated with joint mobilization during the same treatment session. Therapy should also include appropriate ROM, strengthening, and functional exercises, so the patient learns effective control and use of the gained mobility (Box 5.2).

BOX 5.2 Suggested Sequence of Treatment to Gain and Reinforce Functional Mobility

1. Warm the tissues.
2. Relax the muscles.
   - Hold-relax inhibition technique
   - Grade I or II joint oscillation techniques
3. Joint mobilization stretches.
   - Position and dosage for level of tissue tolerance
4. Passive stretch periarticular tissues.
5. Patient actively uses new range.
   - Reciprocal inhibition
   - Active ROM
   - Functional activities
6. Maintain new range; patient instruction.
   - Self-stretching
   - Auto-mobilization
   - Active, resistive ROM
   - Functional activities using the new range

Mobilization with Movement: Principles of Application

Brian Mulligan's concept of mobilization with movement (MWM) is the natural continuance of progression in the development of manual therapy from active self-stretching exercises to therapist-applied passive physiological movement to passive accessory mobilization techniques.[21] MWM is the concurrent application of pain-free accessory mobilization with active and/or passive physiological movement.[23] Passive end-range overpressure or stretching is then applied without pain as a barrier. These techniques are applicable when:

- No contraindication for manual therapy exists (described earlier in the chapter).
- A full orthopedic examination has been completed, and evaluation of the results indicate local musculoskeletal pathology.
- A specific biomechanical analysis reveals localized loss of movement and/or pain associated with function.
- No pain is produced during or immediately after application of the technique.[20]

Principles and Application of MWM in Clinical Practice

Comparable sign. One or more *comparable signs* are identified during the examination.[11] A comparable sign is a positive test sign that can be repeated after a therapeutic maneuver to determine the effectiveness of the maneuver. For example, a comparable sign may include loss of joint play movement, loss of ROM, or pain associated with movement during specific functional activities, such as lateral elbow pain

with resisted wrist extension, painful restriction of ankle dorsiflexion, or pain with overhead reaching.

Passive techniques. A passive joint mobilization is applied using the principles described in the previous section following the principles of Kaltenborn.[15] Utilizing knowledge of joint anatomy and mechanics, a sense of tissue tension, and sound clinical reasoning, the therapist investigates various combinations of parallel or perpendicular accessory glides to find the pain-free direction and grade of accessory movement. This may be a glide, spin, distraction, or combination of movements. This accessory motion must be pain-free.[23]

Accessory glide with active comparable sign. While the therapist sustains the pain-free accessory force, the patient is requested to perform the comparable sign. The comparable sign should now be significantly improved—that is, there should be increased ROM, and the motion should *be free of the original pain.*[23]

No pain. The therapist must continuously monitor the patient's reaction to ensure no pain is produced. Failure to improve the comparable sign would indicate that the therapist has not found the correct direction of accessory movement, the grade of movement, or that the technique is not indicated.

Repetitions. The previously restricted and/or painful motion or activity is repeated 6 to 10 times by the patient while the therapist continues to maintain the appropriate accessory mobilization. Further gains are expected with repetition during a treatment session, particularly when *pain-free* passive overpressure is applied to achieve end-range loading.

Description of techniques. Techniques applicable to the extremity joints are described throughout this text in the treatment sections for various conditions (see Chapters 17 through 22).

Patient Response and Progression

Pain as a guide. Successful MWM techniques should render the comparable sign painless while significantly improving function during the application of the technique.

Self treatment. Once patient response is determined, self-treatment is often possible using MWM principles with sports-type adhesive tape and/or the patient providing the mobilization component of the MWM concurrent with the active physiological movement.[9]

Total program. Having restored articular function with MWMs, the patient is progressed through the ensuing rehabilitation sequences of the recovery of muscular power, endurance, and neural control. Sustained improvements are necessary to justify ongoing intervention.

Theoretical Framework

Mulligan postulated a positional fault model to explain the results gained through his concept. Alternatively, inappropriate joint tracking mechanisms due to an altered instantaneous axis of rotation and neurophysiological response models have also been considered.[9,20,21,24] For further details of the application of the Mulligan concept as it applies to the spine and extremities, refer to *Manual Therapy, "NAGS," "SNAGS," "MWMS," etc.*[23]

FOCUS ON EVIDENCE

Early research on the MWM approach confirms its benefits; however, the mechanism by which it affects the musculoskeletal system, whether mechanical or physiological, has yet to be fully determined.[3,16,25,27,28,31] A study by Paungmali and associates[27] measured a significant reduction in pain, increased grip strength, and increased sympathetic nervous system response immediately following MWM for chronic lateral epicondylalgia compared with a placebo intervention, results that were similar to those in studies of spinal manipulation. They interpreted this to imply that there is a multisystem response to manipulation whether the spine or the elbow is manipulated.

Peripheral Joint Mobilization Techniques

The following are suggested joint distraction and gliding techniques for use by entry-level therapists and those attempting to gain a foundation in joint mobilization of extremity joints. A variety of adaptations can be made from these techniques. Some adaptations are described in the respective chapters in which specific impairments and interventions are discussed (see Chapters 17 through 22). The distraction and glide techniques should be applied with respect to the dosage, frequency, progression, precautions, and procedures as described earlier in this chapter. Mobilization and manipulation/HVT techniques for the spine are described in Chapter 16.

NOTE: Terms, such as proximal hand, distal hand, lateral hand, or other descriptive terms, indicate that the therapist should use the hand that is more proximal, distal, or lateral to the patient or the patient's extremity.

Shoulder Girdle Complex

Joints of the shoulder girdle consist of three synovial articulations—sternoclavicular, acromioclavicular, and glenohumeral—and the functional articulation of the scapula gliding on the thorax. (Fig. 5.13) To gain full elevation of the humerus, the accessory and component motions of clavicular elevation and rotation, scapular rotation, and external rotation of the humerus as well as adequate joint play are necessary. The clavicular and scapular techniques are described following the glenohumeral joint techniques. For a review of the mechanics of the shoulder complex, see Chapter 17.

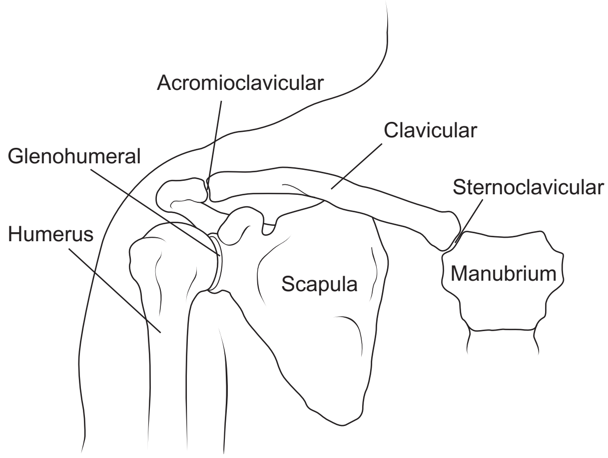

FIGURE 5.13 Bones and joints of the shoulder girdle complex.

Glenohumeral Joint

The concave glenoid fossa receives the convex humeral head.

Resting position. The shoulder is abducted 55°, horizontally adducted 30°, and rotated so the forearm is in the horizontal plane with respect to the body (called plane of the scapula).

Treatment plane. The treatment plane is in the glenoid fossa and moves with the scapula as it rotates.

Stabilization. Fixate the scapula with a belt or have an assistant help.

Glenohumeral Distraction (Fig. 5.14) VIDEO 5.1

Indications

Testing; initial treatment (sustained grade II); pain control (grade I or II oscillations); general mobility (sustained grade III).

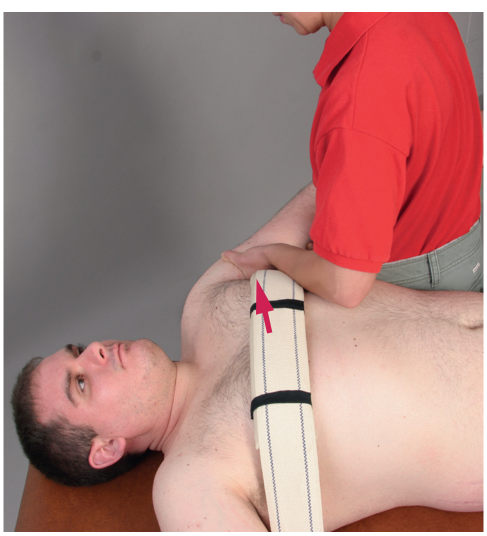

FIGURE 5.14 Glenohumeral joint: distraction in resting position. Note that the force is perpendicular to the T.P. in the glenoid fossa.

Patient Position

Supine, with arm in the resting position. Support the forearm between your trunk and elbow.

Hand Placement

- Use the hand nearer the part being treated (e.g., left hand if treating the patient's left shoulder) and place it in the patient's axilla with your thumb just distal to the joint margin anteriorly and fingers posteriorly.
- Your other hand supports the humerus from the lateral surface.

Mobilizing Force

With the hand in the axilla, move the humerus laterally.

NOTE: The entire arm moves in a translatoric motion away from the plane of the glenoid fossa. Distractions may be performed with the humerus in any position (see Figs. 5.17, 5.19, and 17.20). You must be aware of the amount of scapular rotation and adjust the distraction force against the humerus, so it is perpendicular to the plane of the glenoid fossa.

Glenohumeral Caudal Glide in Resting Position (Fig. 5.15) VIDEO 5.2

Indications

To increase abduction (sustained grade III); to reposition the humeral head if superiorly positioned.

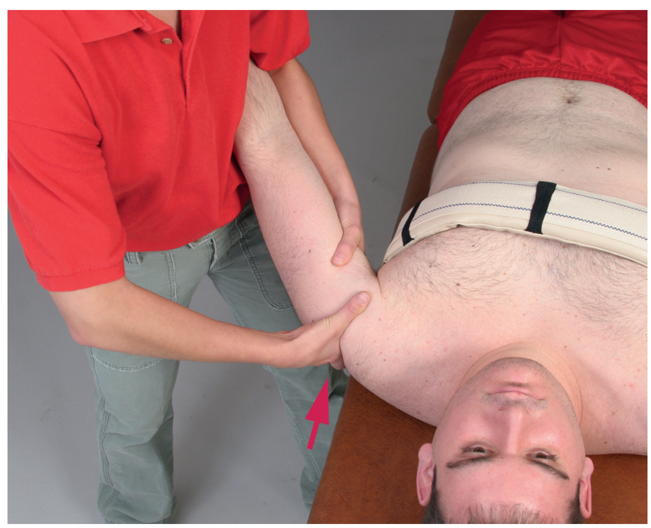

FIGURE 5.15 Glenohumeral joint: caudal glide in the resting position. Note that the distraction force is applied by the hand in the axilla, and the caudal glide force is from the hand superior to the humeral head.

Patient Position

Supine, with arm in the resting position. Support the forearm between your trunk and elbow.

Hand Placement

- Place one hand in the patient's axilla to provide a grade I distraction.
- The web space of your other hand is placed just distal to the acromion process.

Mobilizing Force
With the superiorly placed hand, glide the humerus in an inferior direction.

Glenohumeral Caudal Glide (Long Axis Traction)

Hand Placement
Supine, with arm in the resting position. Support the forearm between your trunk and elbow.

Mobilizing Force
The force comes from the hand around the arm, pulling caudally as you shift your body weight inferiorly.

Glenohumeral Caudal Glide Progression (Fig. 5.16)

Indication
To increase abduction.

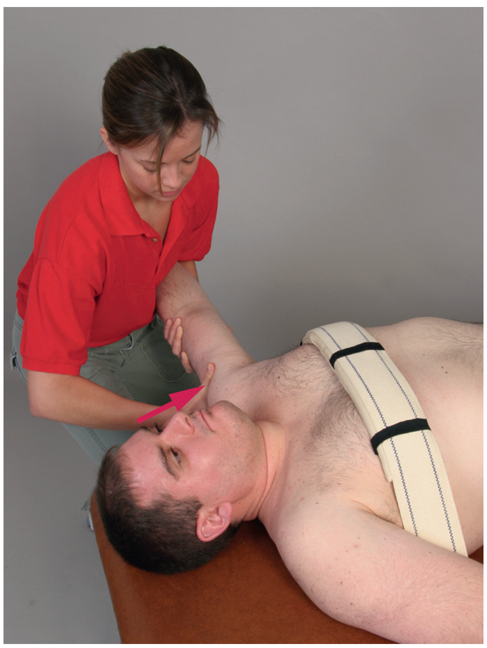

FIGURE 5.16 Glenohumeral joint: caudal glide with the shoulder near 90°.

Patient Position
- Supine or sitting, with the arm abducted to the end of its available range.
- External rotation of the humerus should be added to the end-range position as the arm approaches and goes beyond 90°.

Therapist Position and Hand Placement
- With the patient supine, stand facing the patient's feet and stabilize the patient's arm against your trunk with the hand farthest from the patient. Slight lateral motion of your trunk provides grade I distraction.
- With the patient sitting, stand behind the patient and cradle the distal humerus with the hand farthest from the patient; this hand provides a grade I distraction.
- Place the web space of your other hand just distal to the acromion process on the proximal humerus.

Mobilizing Force
With the hand on the proximal humerus, glide the humerus in an inferior direction with respect to the scapula.

Glenohumeral Elevation Progression (Fig. 5.17)

Indication
To increase elevation beyond 90° of abduction.

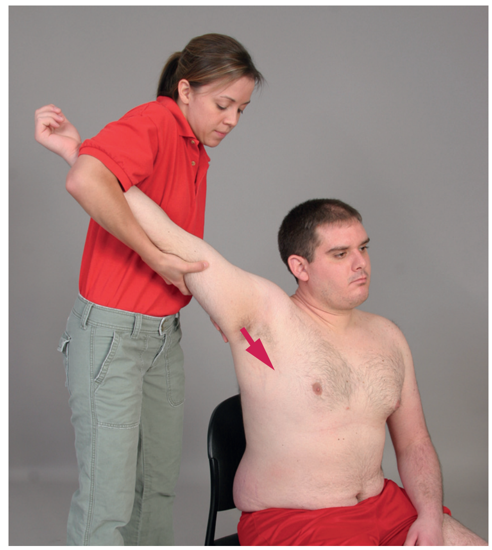

FIGURE 5.17 Glenohumeral joint: elevation progression in the sitting position. This is used when the range is greater than 90°. Note the externally rotated position of the humerus; pressure against the head of the humerus is toward the axilla.

Patient Position
Supine or sitting, with the arm abducted and externally rotated to the end of its available range.

Therapist Position and Hand Placement
- Hand placement is the same as for caudal glide progression.
- Adjust your body position so the hand applying the mobilizing force is aligned with the treatment plane in the glenoid fossa.
- With the hand grasping the elbow, apply a grade I distraction force.

Mobilizing Force
- With the hand on the proximal humerus, glide the humerus in a progressively anterior direction against the inferior folds of the capsule in the axilla.
- The direction of force with respect to the patient's body depends on the amount of upward rotation and protraction of the scapula.

Glenohumeral Posterior Glide, Resting Position (Fig. 5.18) VIDEO 5.3

Indications
To increase flexion; to increase internal rotation.

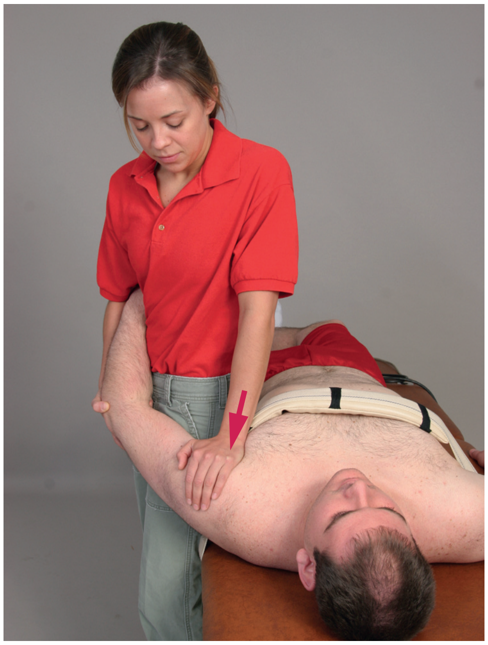

FIGURE 5.18 Glenohumeral joint: posterior glide in the resting position.

Patient Position

Supine, with the arm in resting position.

Therapist Position and Hand Placement

- Stand with your back to the patient, between the patient's trunk and arm.
- Support the arm against your trunk, grasping the distal humerus with your lateral hand. This position provides grade I distraction to the joint.
- Place the lateral border of your top hand just distal to the anterior margin of the joint, with your fingers pointing superiorly. This hand gives the mobilizing force.

Mobilizing Force

Glide the humeral head posteriorly by moving the entire arm as you bend your knees.

Glenohumeral Posterior Glide Progression (Fig. 5.19)

Indications

To increase posterior gliding when flexion approaches 90°; to increase horizontal adduction.

Patient Position

Supine, with the arm flexed to 90° and internally rotated and with the elbow flexed. The arm may also be placed in horizontal adduction.

Hand Placement

- Place padding under the scapula for stabilization.
- Place one hand across the proximal surface of the humerus to apply a grade I distraction.
- Place your other hand over the patient's elbow.
- A belt placed around your pelvis and the patient's humerus may be used to apply the distraction force.

FIGURE 5.19 Glenohumeral joint: posterior glide progression. **(A)** One hand or **(B)** a belt is used to exert a grade I distraction force.

Mobilizing Force

Glide the humerus posteriorly by pushing down at the elbow through the long axis of the humerus.

Glenohumeral Anterior Glide, Resting Position (Fig. 5.20) VIDEO 5.4

Indications

To increase extension; to increase external rotation.

Patient Position

Prone, with the arm in resting position over the edge of the treatment table, supported on your thigh. Stabilize the acromion with padding. Supine position may also be used.

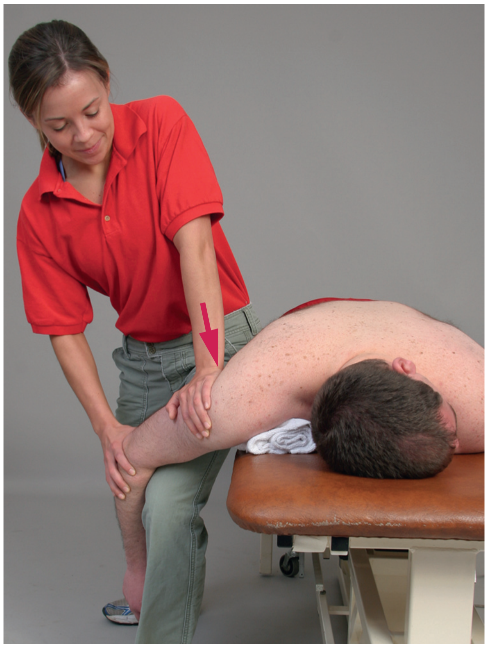

FIGURE 5.20 Glenohumeral joint: anterior glide in the resting position.

Therapist Position and Hand Placement

- Stand facing the top of the table with the leg closer to the table in a forward stride position.
- Support the patient's arm against your thigh with your outside hand; the arm positioned on your thigh provides a grade I distraction.
- Place the ulnar border of your other hand just distal to the posterior angle of the acromion process, with your fingers pointing superiorly; this hand gives the mobilizing force.

Mobilizing Force

Glide the humeral head in an anterior and slightly medial direction. Bend both knees so the entire arm moves anteriorly.

PRECAUTION: Do not lift the arm at the elbow and, thereby, cause angulation of the humerus. Such angulation could lead to anterior subluxation or dislocation of the humeral head. Do not use this position to progress external rotation. Placing the shoulder in 90° abduction with external rotation and applying an anterior glide may cause anterior subluxation of the humeral head.

Glenohumeral External Rotation Progressions (Fig. 5.21) VIDEO 5.5

Indication

To increase external rotation.

Techniques

Because of the danger of subluxation when applying an anterior glide with the humerus externally rotated, use a distraction progression or elevation progression to gain range.

- Distraction progression: Begin with the shoulder in resting position; externally rotate the humerus to end-range; and then apply a grade III distraction perpendicular to the treatment plane in the glenoid fossa.
- Elevation progression (see Fig. 5.17): This technique incorporates end-range external rotation.

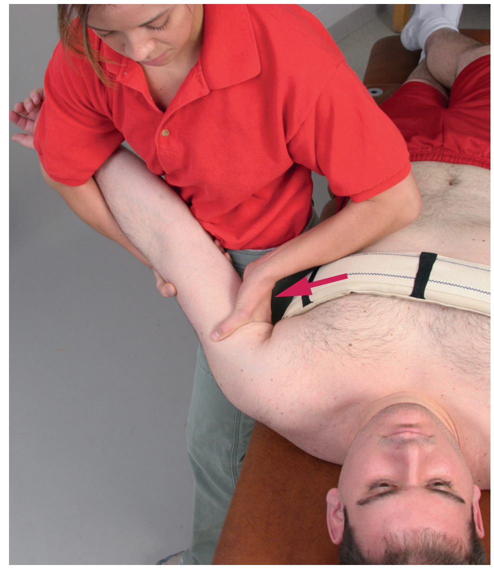

FIGURE 5.21 Glenohumeral joint: distraction for external rotation progression. Note that the humerus is positioned in the resting position with maximum external rotation prior to the application of distraction stretch force.

Acromioclavicular Joint

Indication. To increase mobility of the joint.

Stabilization. Fixate the scapula with your more lateral hand around the acromion process.

Anterior Glide of Clavicle on Acromion (Fig. 5.22)

Patient Position

Sitting or prone.

Hand Placement

- With the patient sitting, stand behind the patient and stabilize the acromion process with the fingers of your lateral hand.
- The thumb of your other hand pushes downward through the upper trapezius and is placed posteriorly on the clavicle, just medial to the joint space.
- With the patient prone, stabilize the acromion with a towel roll under the shoulder.

Mobilizing Force

Push the clavicle anteriorly with your thumb.

Sternoclavicular Joint

Joint surfaces. The proximal articulating surface of the clavicle is convex superiorly/inferiorly and concave anteriorly/posteriorly with an articular disk between it and the manubrium of the sternum.

FIGURE 5.22 Acromioclavicular joint: anterior glide.

Treatment plane. For protraction/retraction, the treatment plane is in the clavicle. For elevation/depression, the treatment plane is in the manubrium

Patient position and stabilization. Supine; the thorax provides stability to the sternum.

Sternoclavicular Posterior Glide and Superior Glide (Fig. 5.23)

Indications

Posterior glide to increase retraction; superior glide to increase depression of the clavicle.

Hand Placement

- Place your thumb on the anterior surface of the proximal end of the clavicle.

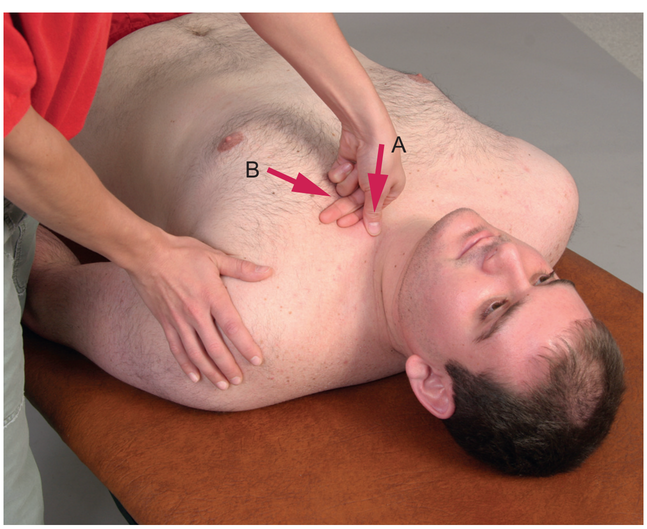

FIGURE 5.23 Sternoclavicular joint: posterior and superior glides. **(A)** Press down with the thumb for posterior glide. **(B)** Press upward with the index finger for superior glide.

- Flex your index finger and place the middle phalanx along the caudal surface of the clavicle to support the thumb.

Mobilizing Force

- Posterior glide: Push with your thumb in a posterior direction.
- Superior glide: Push with your index finger in a superior direction

Sternoclavicular Anterior Glide and Caudal (Inferior) Glide (Fig. 5.24)

Indications

Anterior glide to increase protraction; caudal glide to increase elevation of the clavicle.

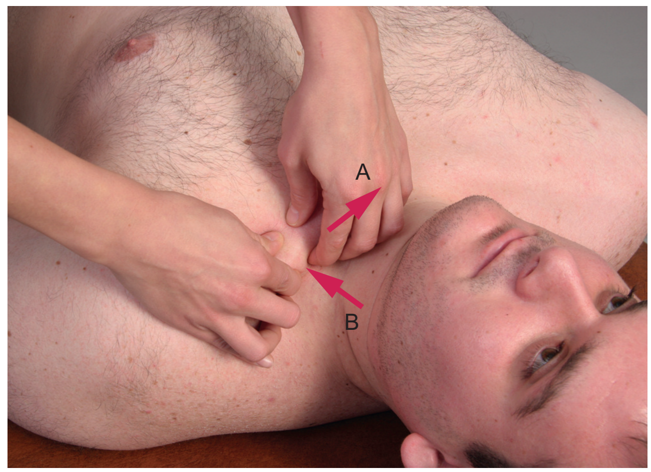

FIGURE 5.24 Sternoclavicular joint: anterior and inferior glides. **(A)** Pull the clavicle upward for an anterior glide. **(B)** Press caudalward with the curled fingers for an inferior glide.

Hand Placement

Your fingers are placed superiorly and thumb inferiorly around the clavicle.

Mobilizing Force

- Anterior glide: lift the clavicle anteriorly with your fingers and thumb.
- Caudal glide: press the clavicle inferiorly with your fingers.

Scapulothoracic Soft-Tissue Mobilization (Fig. 5.25) VIDEO 5.6

The scapulothoracic articulation is not a true joint, but the soft tissue and muscles supporting the articulation are stretched to obtain scapular motions of elevation, depression, protraction, retraction, upward and downward rotation, and winging for normal shoulder girdle mobility.

Patient position. If there is considerable restriction in mobility, begin prone and progress to side-lying, with the patient facing you. Support the weight of the patient's arm by draping it over your inferior arm and allowing it to hang so the scapular muscles are relaxed.

FIGURE 5.25 Scapulothoracic articulation: elevation, depression, protraction, retraction, upward and downward rotations, and winging.

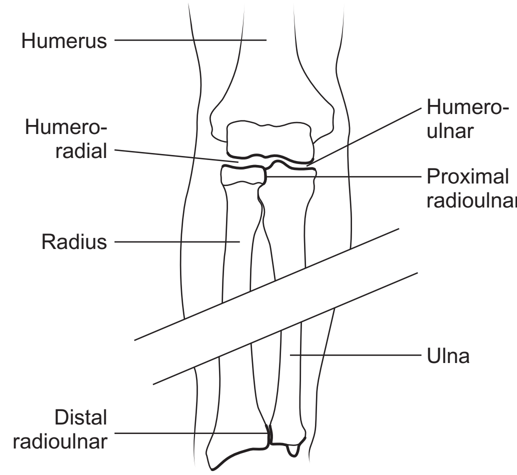

FIGURE 5.26 Bones and joints of the elbow complex.

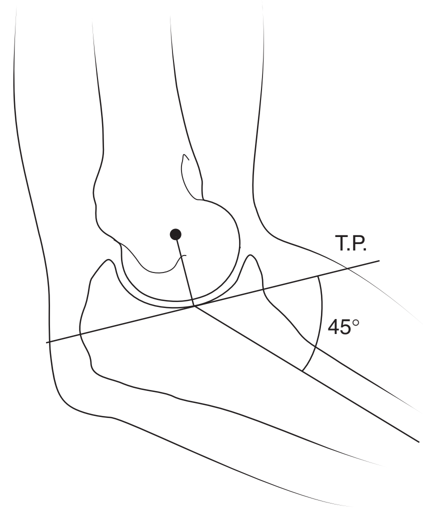

FIGURE 5.27 Lateral view of the humeroulnar joint, depicting the T.P.

Hand placement. Place your superior hand across the acromion process to control the direction of motion. With the fingers of your inferior hand, scoop under the medial border and under the inferior angle of the scapula.

Mobilizing force. Move the scapula in the desired direction by lifting from the inferior angle or by pushing on the acromion process.

Elbow and Forearm Complex

The elbow and forearm complex consists of four joints: humeroulnar, humeroradial, proximal radioulnar, and distal radioulnar (Fig. 5.26). For full elbow flexion and extension, accessory motions of varus and valgus (with radial and ulnar glides) are necessary. The techniques for each of the joints as well as accessory motions are described in this section. For a review of the joint mechanics, see Chapter 18.

Humeroulnar Articulation

The convex trochlea articulates with the concave olecranon fossa.

Resting position. Elbow is flexed 70°, and forearm is supinated 10°.

Treatment plane. The treatment plane is in the olecranon fossa, angled approximately 45° from the long axis of the ulna (Fig. 5.27).

Stabilization. Fixate the humerus against the treatment table with a belt or use an assistant to hold it. The patient may roll onto his or her side and fixate the humerus with the contralateral hand if muscle relaxation can be maintained around the elbow joint being mobilized.

Humeroulnar Distraction and Progression (Fig. 5.28 A) VIDEO 5.7

Indications

Testing; initial treatment (sustained grade II); pain control (grade I or II oscillation); to increase flexion or extension (grade III or IV).

Patient Position

Supine, with the elbow over the edge of the treatment table or supported with padding just proximal to the olecranon process. Rest the patient's wrist against your shoulder, allowing the elbow to be in resting position for the initial treatment. To stretch into either flexion or extension, position the joint at the end of its available range.

FIGURE 5.28 Humeroulnar joint: (A) distraction and

Hand Placement

When in the resting position or at end-range flexion, place the fingers of your medial hand over the proximal ulna on the volar surface; reinforce it with your other hand. When at end-range extension, stand and place the base of your proximal hand over the proximal portion of the ulna and support the distal forearm with your other hand.

Mobilizing Force

Apply force against the proximal ulna at a 45° angle to the shaft of the bone.

Humeroulnar Distal Glide (Fig. 5.28 B)

Indication

To increase flexion.

FIGURE 5.28 (B) distraction with distal glide (scoop motion).

Patient Position and Hand Placement

Supine, with the elbow over the edge of the treatment table. Begin with the elbow in resting position. Progress by positioning it at the end-range of flexion. Place the fingers of your medial hand over the proximal ulna on the volar surface; reinforce it with your other hand.

Mobilizing Force

First apply a distraction force to the joint at a 45° angle to the ulna, then while maintaining the distraction, direct the force in a distal direction along the long axis of the ulna using a scooping motion.

Humeroulnar Radial Glide

Indication

To increase varus. This is an accessory motion of the joint that accompanies elbow flexion and is, therefore, used to progress flexion.

Patient Position

- Side-lying on the arm to be mobilized, with the shoulder laterally rotated and the humerus supported on the table.
- Begin with the elbow in resting position; progress to end-range flexion.

Hand Placement

Place the base of your proximal hand just distal to the elbow; support the distal forearm with your other hand.

Mobilizing Force

Apply force against the ulna in a radial direction.

Humeroulnar Ulnar Glide

Indication

To increase valgus. This is an accessory motion of the joint that accompanies elbow extension and is, therefore, used to progress extension.

Patient Position

- Same as for radial glide except a block or wedge is placed under the proximal forearm for stabilization (using distal stabilization).
- Initially, the elbow is placed in resting position and is progressed to end-range extension.

Mobilizing Force

Apply force against the distal humerus in a radial direction, causing the ulna to glide ulnarly.

Humeroradial Articulation VIDEO 5.8

The convex capitulum articulates with the concave radial head (see Fig. 5.26).

Resting position. Elbow is extended, and forearm is supinated to the end of the available range.

Treatment plane. The treatment plane is in the concave radial head perpendicular to the long axis of the radius.

Stabilization. Fixate the humerus with one of your hands.

Humeroradial Distraction (Fig. 5.29)

Indications

To increase mobility of the humeroradial joint; to manipulate a pushed elbow (proximal displacement of the radius).

FIGURE 5.29 Humeroradial joint: distraction.

Patient Position

Supine or sitting, with the arm resting on the treatment table.

Therapist Position and Hand Placement

- Position yourself on the ulnar side of the patient's forearm so you are between the patient's hip and upper extremity.
- Stabilize the patient's humerus with your superior hand.
- Grasp around the distal radius with the fingers and thenar eminence of your inferior hand. Be sure you are not grasping around the distal ulna.

Mobilizing Force

Pull the radius distally (long-axis traction causes joint traction).

Humeroradial Dorsal/Volar Glides (Fig. 5.30)

Indications

Dorsal glide head of the radius to increase elbow extension; volar glide to increase flexion.

Patient Position

Supine or sitting with the elbow extended and supinated to the end of the available range.

Hand Placement

- Stabilize the humerus with your hand that is on the medial side of the patient's arm.
- Place the palmar surface of your lateral hand on the volar aspect and your fingers on the dorsal aspect of the radial head.

Mobilizing Force

- Move the radial head dorsally with the palm of your hand or volarly with your fingers.
- If a stronger force is needed for the volar glide, realign your body and push with the base of your hand against the dorsal surface in a volar direction.

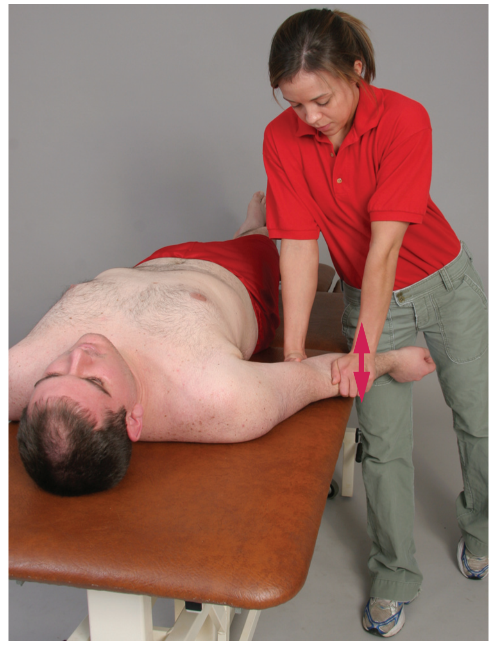

FIGURE 5.30 Humeroradial joint: dorsal and volar glides. This may also be done sitting, as in Figure 5.32, with the elbow positioned in extension and the humerus stabilized by the proximal hand (rather than the ulna).

Humeroradial Compression (Fig. 5.31)

Indication

To reduce a pulled elbow subluxation.

Patient Position

Sitting or supine.

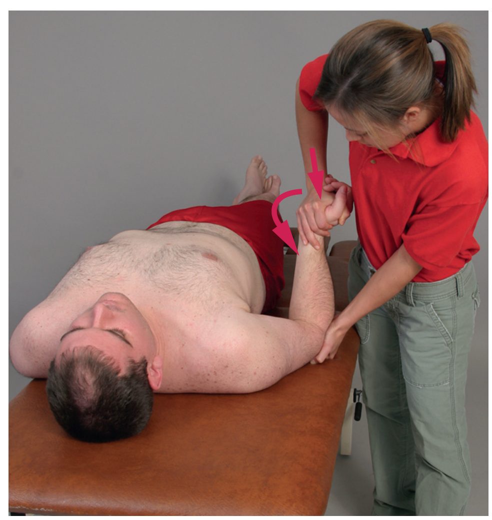

FIGURE 5.31 Humeroradial joint: compression mobilization. This is a quick thrust with simultaneous supination and compression of the radius.

Hand Placement

- Approach the patient right hand to right hand, or left hand to left hand. Stabilize the elbow posteriorly with the other hand. If supine, the stabilizing hand is under the elbow supported on the treatment table.
- Place your thenar eminence against the patient's thenar eminence (locking thumbs).

Mobilizing Force

Simultaneously, extend the patient's wrist, push against the thenar eminence, and compress the long axis of the radius while supinating the forearm.

NOTE: To replace an acute subluxation, a high-velocity thrust is used.

Proximal Radioulnar Joint

The convex rim of the radial head articulates with the concave radial notch on the ulna (see Fig. 5.26).

Resting position. The elbow is flexed 70° and the forearm supinated 35°.

Treatment plane. The treatment plane is in the radial notch of the ulna, parallel to the long axis of the ulna.

Stabilization. Proximal ulna is stabilized.

Proximal Radioulnar Dorsal/Volar Glides (Fig. 5.32) VIDEO 5.8

Indications

Dorsal glide to increase pronation; volar glide to increase supination.

FIGURE 5.32 Proximal radioulnar joint: dorsal and volar glides.

Patient Position

- Sitting or supine, begin with the elbow flexed 70° and the forearm supinated 35°.
- Progress by placing the forearm at the limit of the range of pronation or supination prior to administering the respective glide.

Hand Placement

- Approach the patient from the dorsal or volar aspect of the forearm. Fixate the ulna with your medial hand around the medial aspect of the forearm.
- With your other hand, grasp the head of the radius between your flexed fingers and palm of your hand.

Mobilizing Force

- Force the radial head volarly or dorsally by pushing with your palm or pulling with your fingers.
- If a stronger force is needed, rather than pulling with your fingers, move to the other side of the patient, switch hands, and apply the force with the palm of your hand.

Distal Radioulnar Joint

The concave ulnar notch of the radius articulates with the convex head of the ulna.

Resting position. The resting position is with the forearm supinated 10°.

Treatment plane. The treatment plane is the articulating surface of the radius, parallel to the long axis of the radius.

Stabilization. Distal ulna.

Distal Radioulnar Dorsal/Volar Glides (Fig. 5.33)

Indications

Dorsal glide to increase supination; volar glide to increase pronation.

FIGURE 5.33 Distal radioulnar joint: dorsal and volar glides.

Patient Position

Sitting, with the forearm on the treatment table. Begin in the resting position and progress to end-range pronation or supination.

Hand Placement

Stabilize the distal ulna by placing the fingers of one hand on the dorsal surface and the thenar eminence and thumb on the

volar surface. Place your other hand in the same manner around the distal radius.

Mobilizing Force

Glide the distal radius dorsally to increase supination or volarly to increase pronation parallel to the ulna.

Wrist and Hand Complex

When mobilizing the wrist, begin with general distractions and glides that include the proximal row and distal row of carpals as a group. For full ROM, individual carpal mobilizations/manipulations may be necessary. They are described following the general mobilizations. For a review of the mechanics of the wrist complex, see Chapter 19 (Fig. 5.34).

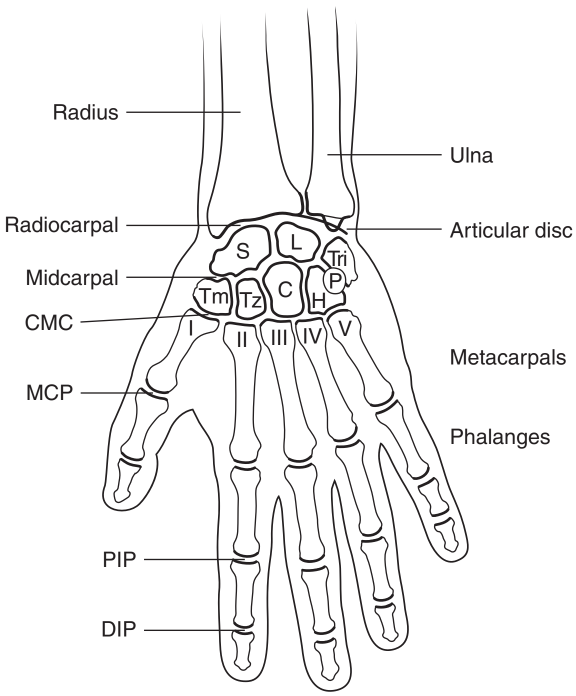

FIGURE 5.34 Bones and joints of the wrist and hand.

Radiocarpal Joint

The concave distal radius articulates with the convex proximal row of carpals, which is composed of the scaphoid, lunate, and triquetrum.

Resting position. The resting position is a straight line through the radius and third metacarpal with slight ulnar deviation.

Treatment plane. The treatment plane is in the articulating surface of the radius perpendicular to the long axis of the radius.

Stabilization. Distal radius and ulna.

Radiocarpal Distraction (Fig. 5.35)

Indications

Testing; initial treatment; pain control; general mobility of the wrist.

FIGURE 5.35 Wrist joint: general distraction.

Patient Position

Sitting, with the forearm supported on the treatment table, wrist over the edge of the table.

Hand Placement

- With the hand closest to the patient, grasp around the styloid processes and fixate the radius and ulna against the table.
- Grasp around the distal row of carpals with your other hand.

Mobilizing Force

Pull in a distal direction with respect to the arm.

Radiocarpal Joint: General Glides and Progression

Indications

Dorsal glide to increase flexion (Fig. 5.36 A); volar glide to increase extension (Fig. 5.36 B); radial glide to increase ulnar deviation; ulnar glide to increase radial deviation (Fig. 5.37).

Patient Position and Hand Placement

Sitting with forearm resting on the table in pronation for the dorsal and volar techniques and in midrange position for the radial and ulnar techniques. Progress by moving the wrist to the end of the available range and gliding in the defined direction. Specific carpal gliding techniques described in the next sections are used to increase mobility at isolated articulations.

Mobilizing Force

The force comes from the hand around the distal row of carpals.

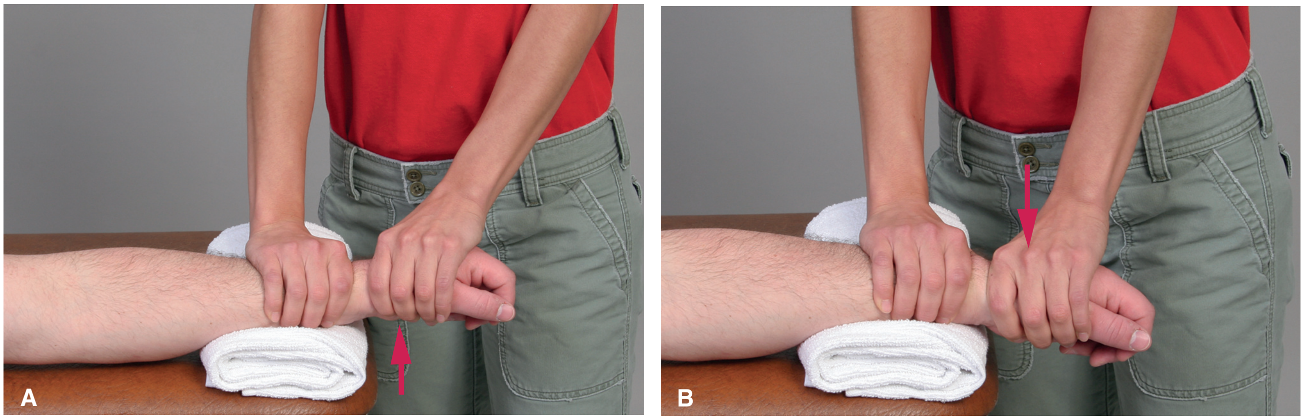

FIGURE 5.36 Wrist joint: general mobilization. **(A)** Dorsal glide. **(B)** Volar glide.

FIGURE 5.37 Wrist joint: general mobilization—ulnar glide.

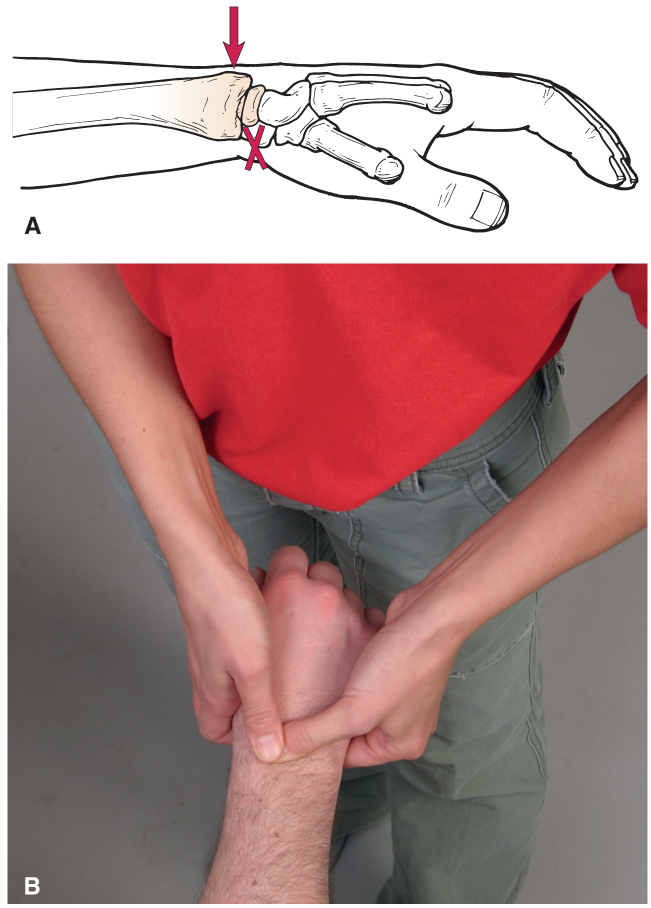

FIGURE 5.38 Specific carpal mobilizations: stabilization of the distal bone and volar glide of the proximal bone. Shown is stabilization of the scaphoid and lunate with the index fingers and a volar glide to the radius with the thumbs to increase wrist flexion: **(A)** drawing of the side view with arrow depicting placement of thumbs on the radius and 'x' depicting placement of stabilizing index fingers; **(B)** illustrates superior view of overlapping thumbs on the radius.

Specific Carpal Mobilizations (Figs. 5.38 and 5.39)

Specific techniques to mobilize individual carpal bones may be necessary to gain full ROM of the wrist. Specific biomechanics of the radiocarpal and intercarpal joints are described in Chapter 19. To glide one carpal on another or on the radius, utilize the following guidelines.

Patient and Therapist Positions

- The patient sits.
- Stand and grasp the patient's hand so the elbow hangs unsupported.
- The weight of the arm provides slight distraction to the joints, so you then need only to apply the glides.

Hand Placement and Indications

Identify the specific articulation to be mobilized and place your index fingers on the volar surface of the bone to be stabilized. Place the overlapping thumbs on the dorsal surface of the bone to be manipulated. The rest of your fingers hold the patient's hand so it is relaxed.

To increase extension. Place the stabilizing index fingers under the bone that is *concave* (on the volar surface). Overlap the thumbs and place on the dorsal surface of the bone that is *convex*. The thumbs provide the manipulating force.

- Thumbs on dorsum of convex scaphoid, index fingers stabilize radius.
- Thumbs on dorsum of convex lunate, index fingers stabilize radius.

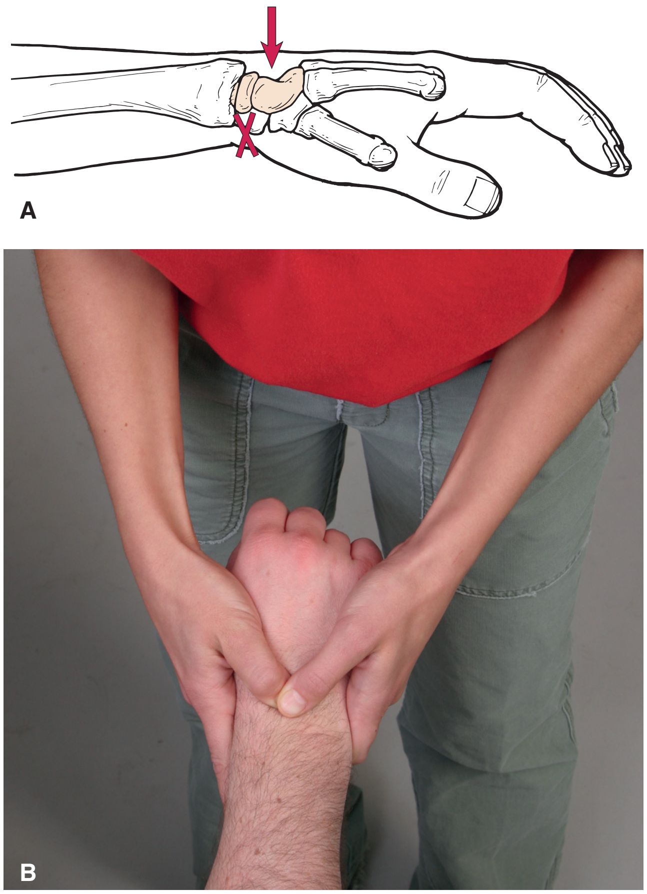

FIGURE 5.39 Specific carpal mobilizations: stabilization of the proximal bone and volar guide of the distal bone. Shown is stabilization of the lunate with the index fingers and volar glide to the capitate with the thumbs to increase extension: (A) drawing of the side view with arrow depicting placement of thumbs on the capitate and 'x' depicting placement of stabilizing index fingers; (B) illustrates superior view of overlapping thumbs on the capitate.

- Thumbs on dorsum of convex scaphoid, index fingers stabilize trapezium-trapezoid unit.
- Thumbs on dorsum of convex capitate, index fingers stabilize lunate (see Fig. 5.39).
- Thumbs on dorsum of convex hamate, index fingers stabilize triquetrum.

To increase flexion. Place the stabilizing index fingers under the bone that is *convex* (on the volar surface), and the mobilizing thumbs overlapped on the dorsal surface of the bone that is *concave*.

- Thumbs on the dorsum of the concave radius, index fingers stabilize scaphoid.
- Thumbs on the dorsum of the concave radius, index fingers stabilize lunate (see Fig. 5.38).
- Thumbs on dorsum of trapezium-trapezoid unit, index fingers stabilize scaphoid.
- Thumbs on dorsum of concave lunate, index fingers stabilize capitate.
- Thumbs on dorsum of concave triquetrum, index fingers stabilize hamate.

Mobilizing Force

- In each case, the force comes from the overlapping thumbs on the dorsal surface.
- By applying force from the dorsal surface, pressure against the nerves, blood vessels, and tendons in the carpal tunnel and Guyon's canal is minimized, and a stronger mobilization force can be used without pain.
- An HVT technique can be used by providing a quick downward and upward flick of your wrists and hands while pressing against the respective carpals.

Ulnar-Meniscal-Triquetral Articulation

To unlock the articular disk, which may block motions of the wrist or forearm, apply a glide of the ulna volarly on a fixed triquetrum (see Fig. 19.7).

Carpometacarpal and Intermetacarpal Joints of Digits II–V

Opening and closing of the hand and maintenance of the arches in the hand requires general mobility between the carpals and metacarpals.

Carpometacarpal Distraction (Fig. 5.40)

Stabilization and Hand Placement

Stabilize the respective carpal with thumb and index finger of one hand. With your other hand, grasp around the proximal portion of a metacarpal.

FIGURE 5.40 Carpometacarpal joint: Distraction.

Mobilizing Force

Apply long-axis traction to the metacarpal.

Carpometacarpal and Intermetacarpal: Volar Glide

Indication

To increase mobility of the arch of the hand.

Stabilization and Hand Placement

Stabilize the carpals with the thumb and index finger of one hand; place the thenar eminence of your other hand along the

dorsal aspect of the metacarpals to provide the mobilization force.

Mobilizing Force

Glide the proximal portion of the metacarpal volar ward. See also the stretching technique for cupping and flattening the arch of the hand described in Chapter 4.

Carpometacarpal Joint of the Thumb

The CMC of the thumb is a saddle joint. The trapezium is concave, and the proximal metacarpal is convex for abduction/adduction. The trapezium is convex, and the proximal metacarpal is concave for flexion/extension.

Resting position. The resting position is midway between flexion and extension and between abduction and adduction.

Stabilization. Fixate the trapezium with the hand that is closer to the patient.

Treatment plane. The treatment plane is in the trapezium for abduction-adduction and in the proximal metacarpal for flexion-extension.

Carpometacarpal Distraction (Thumb)

Indications

Testing; initial treatment; pain control; general mobility.

Patient Position

The patient is positioned with forearm and hand resting on the treatment table.

Hand Placement

- Fixate the trapezium with the hand that is closer to the patient.
- Grasp the patient's metacarpal by wrapping your fingers around it (see Fig. 5.41 A).

Mobilizing Force

Apply long-axis traction to separate the joint surfaces.

Carpometacarpal Glides (Thumb) (Fig. 5.41)

Indications

- Ulnar glide to increase flexion
- Radial glide to increase extension
- Dorsal glide to increase abduction
- Volar glide to increase adduction

Patient Position and Hand Placement

- Stabilize the trapezium by grasping it directly or by wrapping your fingers around the distal row of carpals.
- Place the thenar eminence of your other hand against the base of the patient's first metacarpal on the side opposite the desired glide. For example, as pictured in Fig. 5.41 A, the surface of the thenar eminence is on the radial side of the metacarpal to cause an ulnar glide.

Mobilizing Force

Apply the force with your thenar eminence against the base of the metacarpal. Adjust your body position to line up the force as illustrated in Figure 5.41 A through D.

FIGURE 5.41 Carpometacarpal joint of the thumb. **(A)** Ulnar glide to increase flexion. **(B)** Radial glide to increase extension. **(C)** Dorsal glide to increase abduction. **(D)** Volar glide to increase adduction. Note that the thumb of the therapist is placed in the web space between the index and thumb of the patient's hand to apply a volar glide.

Metacarpophalangeal and Interphalangeal Joints of the Fingers

In all cases, the distal end of the proximal articulating surface is convex, and the proximal end of the distal articulating surface is concave.

NOTE: Because all the articulating surfaces are the same for the digits, all techniques are applied in the same manner to each joint.

Resting position. The resting position is in light flexion for all joints.

Treatment plane. The treatment plane is in the distal articulating surface.

Stabilization. Rest the forearm and hand on the treatment table; fixate the proximal articulating surface with the fingers of one hand.

Metacarpophalangeal and Interphalangeal Distraction (Fig. 5.42)

Indications

Testing; initial treatment; pain control; general mobility.

FIGURE 5.42 Metacarpophalangeal joint: distraction.

Hand Placement

Use your proximal hand to stabilize the proximal bone; wrap the fingers and thumb of your other hand around the distal bone close to the joint.

Mobilizing Force

Apply long-axis traction to separate the joint surface.

Metacarpophalangeal and Interphalangeal Glides and Progression

Indications

- Volar glide to increase flexion (Fig. 5.43)
- Dorsal glide to increase extension

FIGURE 5.43 Metacarpophalangeal joint: volar glide.

- Radial or ulnar glide (depending on finger) to increase abduction or adduction.

Mobilizing Force

The glide force is applied by the thumb or thenar eminence against the proximal end of the bone to be moved. Progress by taking the joint to the end of its available range and applying slight distraction and the glide force. Rotation may be added prior to applying the gliding force.

Hip Joint

The concave acetabulum receives the convex femoral head. (Fig. 5.44) Biomechanics of the hip joint are reviewed in Chapter 20.

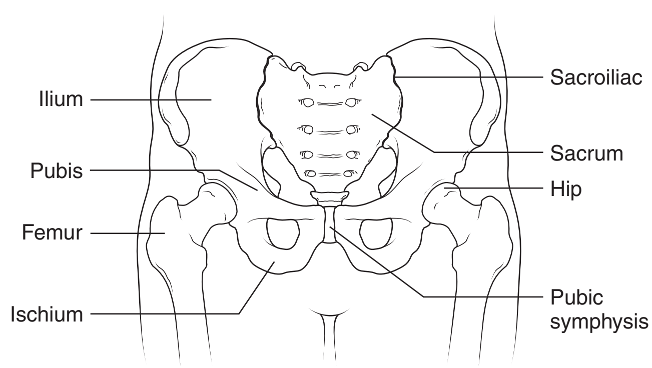

FIGURE 5.44 Bones and joints of the pelvis and hip.

Resting position. The resting position is hip flexion 30°, abduction 30°, and slight external rotation.

Stabilization. Fixate the pelvis to the treatment table with belts.

Treatment plane. The treatment is in the acetabulum.

Hip Distraction of the Weight-Bearing Surface, Caudal Glide (Fig. 5.45)

Because of the deep configuration of this joint, traction applied perpendicular to the treatment plane causes lateral glide of the superior, weight-bearing surface. To obtain separation of the weight-bearing surface, a caudal glide is used.

FIGURE 5.45 Hip joint: pistraction of the weight-bearing surface.

Indications

Testing; initial treatment; pain control; general mobility.

Patient Position

Supine, with the hip in resting position and the knee extended.

PRECAUTION: In the presence of knee dysfunction, this position should not be used; see alternate position following.

Therapist Position and Hand Placement

Stand at the end of the treatment table; place a belt around your trunk, then cross the belt over the patient's foot and around the ankle. Place your hands proximal to the malleoli, under the belt. The belt allows you to use your body weight to apply the mobilizing force.

Mobilizing Force

Apply a long-axis traction by pulling on the leg as you lean backward.

Alternate Position and Technique for Hip Caudal Glide

- Patient supine with hip and knee flexed and foot resting on table.
- Wrap your hands around the epicondyles of the femur and distal thigh. Do not compress the patella.
- The force comes from your hands and is applied in a caudal direction as you lean backward.

Hip Posterior Glide (Fig. 5.46) VIDEO 5.9

Indications

To increase flexion; to increase internal rotation.

Patient Position

- Supine, with hips at the end of the table.
- The patient helps stabilize the pelvis and lumbar spine by flexing the opposite hip and holding the thigh against the chest with the hands.
- Initially, the hip to be mobilized is in resting position; progress to the end of the range.

FIGURE 5.46 Hip joint: posterior glide.

Therapist Position and Hand Placement

- Stand on the medial side of the patient's thigh.
- Place a belt around your shoulder and under the patient's thigh to help hold the weight of the lower extremity.
- Place your distal hand under the belt and distal thigh. Place your proximal hand on the anterior surface of the proximal thigh.

Mobilizing Force

Keep your elbows extended and flex your knees; apply the force through your proximal hand in a posterior direction.

Hip Anterior Glide (Fig. 5.47) VIDEO 5.10

Indications

To increase extension; to increase external rotation.

Patient Position

Prone, with the trunk resting on the table and hips over the edge. The opposite foot is on the floor.

Therapist Position and Hand Placement

- Stand on the medial side of the patient's thigh.
- Place a belt around your shoulder and the patient's thigh to help support the weight of the leg.

FIGURE 5.47 Hip joint: anterior glide. (A) prone and

- With your distal hand, hold the patient's leg.
- Place your proximal hand posteriorly on the proximal thigh just below the buttock.

Mobilizing Force

Keep your elbow extended and flex your knees; apply the force through your proximal hand in an anterior direction.

Alternate Position

- Position the patient side-lying with the thigh comfortably flexed and supported by pillows.
- Stand posterior to the patient and stabilize the pelvis across the anterior superior iliac spine with your cranial hand.

FIGURE 5.47 (B) side-lying.

- Push against the posterior aspect of the greater trochanter in an anterior direction with your caudal hand.

Knee Joint Complex

The knee joint consists of two articulating surfaces between the femoral condyles and tibial plateaus with a fibrocartilaginous disc between each articulation, as well as the articulation of the patella with the femoral groove (Fig. 5.48). As the knee flexes, medial rotation of the tibia occurs, and as it extends, lateral rotation of the tibia occurs. In addition, the patella must glide caudally against the femur during flexion and glide cranially during extension for normal knee mobility. These mechanics are described in Chapter 21.

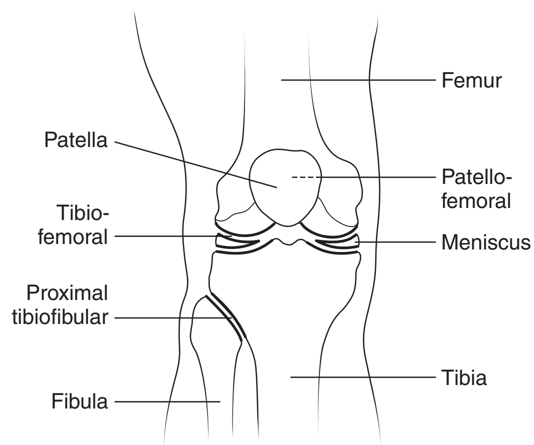

FIGURE 5.48 Bones and joints of the knee and leg.

Tibiofemoral Articulations

The concave tibial plateaus articulate on the convex femoral condyles. Biomechanics of the knee joint are described in Chapter 21.

Resting position. The resting position is 25° flexion.

Treatment plane. The treatment plane is along the surface of the tibial plateaus; therefore, it moves with the tibia as the knee angle changes.

Stabilization. In most cases, the femur is stabilized with a belt or by the table.

Tibiofemoral Distraction: Long-Axis Traction (Fig. 5.49)

Indications

Testing; initial treatment; pain control; general mobility.

Patient Position

- Sitting, supine, or prone, beginning with the knee in the resting position.

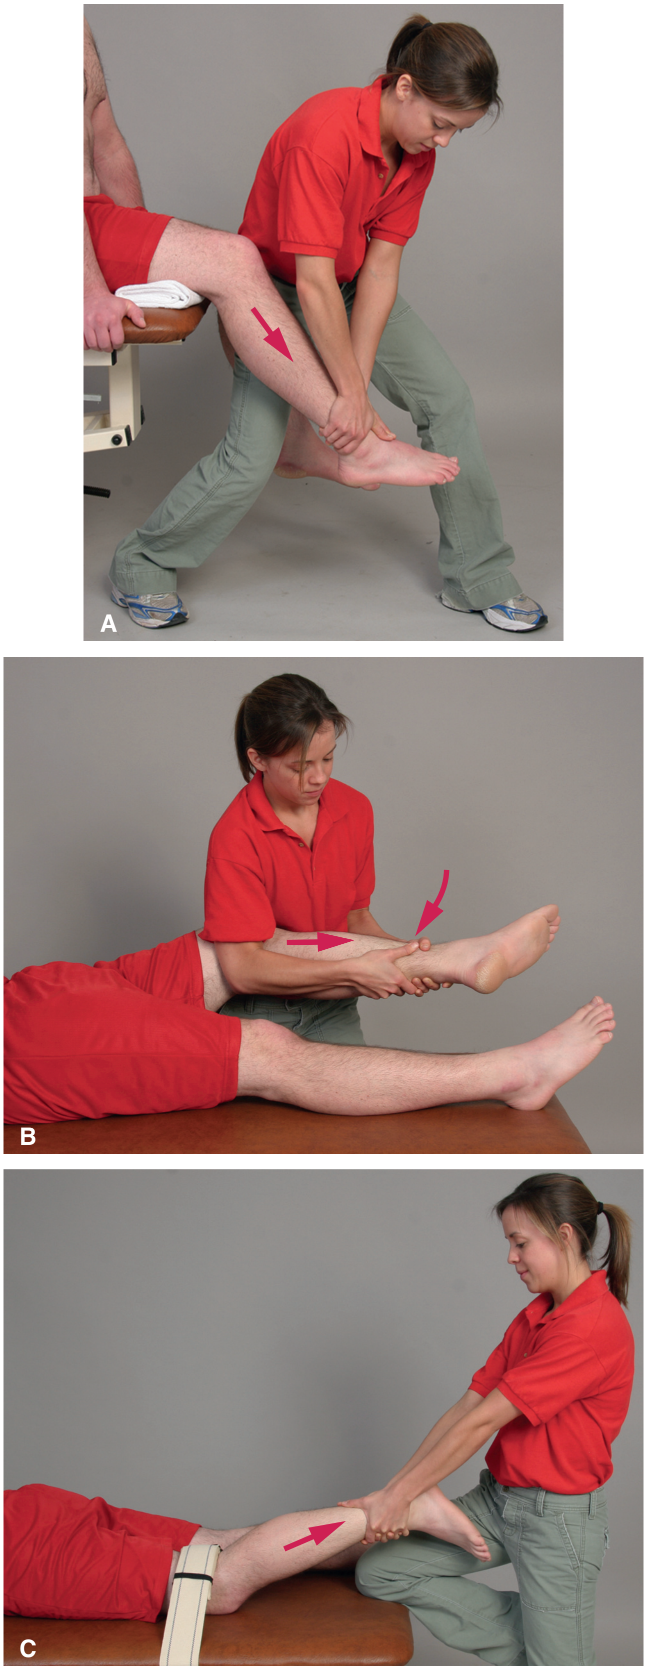

FIGURE 5.49 Tibiofemoral joint: distraction. (A) sitting (B) supine (C) prone

- Progress to positioning the knee at the limit of the range of flexion or extension.
- Rotation of the tibia may be added prior to applying the traction force. Use internal rotation at end-range flexion and external rotation at end-range extension.

Hand Placement

Grasp around the distal leg, proximal to the malleoli with both hands.

Mobilizing Force

Pull on the long axis of the tibia to separate the joint surfaces.

Tibiofemoral Posterior Glide (Fig. 5.50)

Indications

Testing; to increase flexion.

FIGURE 5.50 Tibiofemoral joint: posterior glide (drawer).

Patient Position

Supine, with the foot resting on the table. The position for the drawer test can be used to mobilize the tibia either anteriorly or posteriorly, although no grade I distraction can be applied with the glides.

Therapist Position and Hand Placement

Sit on the table with your thigh fixating the patient's foot. With both hands, grasp around the tibia, fingers pointing posteriorly and thumbs anteriorly.

Mobilizing Force

Extend your elbows and lean your body weight forward; push the tibia posteriorly with your thumbs.

Tibiofemoral Posterior Glide: Alternate Positions and Progression (Fig. 5.51)

Patient Position

- Sitting, with the knee flexed over the edge of the treatment table, beginning in the resting position (Fig. 5.51). Progress to near 90° flexion with the tibia positioned in internal rotation.

FIGURE 5.51 Tibiofemoral joint: posterior glide, sitting.

FIGURE 5.52 Tibiofemoral joint: anterior glide.

- When the knee flexes past 90°, position the patient prone; place a small rolled towel proximal to the patella to minimize compression forces against the patella during the mobilization.

Therapist Position and Hand Placement

- When in the resting position, stand on the medial side of the patient's leg. Hold the distal leg with your distal hand and place the palm of your proximal hand along the anterior border of the tibial plateaus.
- When near 90°, sit on a low stool; stabilize the leg between your knees and place one hand on the anterior border of the tibial plateaus.
- When prone, stabilize the femur with one hand and place the other hand along the border of the tibial plateaus.

Mobilizing Force

- Extend your elbow and lean your body weight onto the tibia, gliding it posteriorly.
- When progressing with medial rotation of the tibia at the end of the range of flexion, the force is applied in a posterior direction against the medial side of the tibia.

Tibiofemoral Anterior Glide (Fig. 5.52) VIDEO 5.11

Indication

To increase extension.

Patient Positions

- Prone, beginning with the knee in resting position; progress to the end of the available range. Place a small pad under the distal femur to prevent patellar compression.
- The drawer test position can also be used. The mobilizing force comes from the fingers on the posterior tibia as you lean backward (see Fig. 5.50).

Hand Placement

Grasp the distal tibia with the hand that is closer to it and place the palm of the proximal hand on the posterior aspect of the proximal tibia.

Mobilizing Force

Apply force with the hand on the proximal tibia in an anterior direction. The force may be directed to the lateral or medial tibial plateau to isolate one side of the joint.

Alternate Position and Technique

- If the patient cannot be positioned prone, position him or her supine with a fixation pad under the tibia.
- The mobilizing force is placed against the femur in a posterior direction.

Patellofemoral Joint

The patella must have mobility to glide distally on the femur for normal knee flexion, and glide proximally for normal knee extension.

Patellofemoral Joint, Distal Glide (Fig. 5.53)

Patient Position

Supine, with knee extended; progress to positioning the knee at the end of the available range in flexion.

Hand Placement

Stand next to the patient's thigh, facing the patient's feet. Place the web space of the hand that is closer to the thigh around the superior border of the patella. Use the other hand for reinforcement.

Mobilizing Force

Glide the patella in a caudal direction, parallel to the femur.

FIGURE 5.53 Patellofemoral joint: distal glide.

PRECAUTION: Do not compress the patella into the femoral condyles while performing this technique.

Patellofemoral Medial or Lateral Glide (Fig. 5.54)

Indication

To increase patellar mobility.

FIGURE 5.54 Patellofemoral joint: lateral glide.

Patient Position

Supine with the knee extended. Side-lying may be used to apply a medial glide (see Fig. 21.3).

Hand Placement

Place the heel of your hand along either the medial or lateral aspect of the patella. Stand on the opposite side of the table to position your hand along the medial border and on the same side of the table to position your hand along the lateral border. Place the other hand under the femur to stabilize it.

Mobilizing Force

Glide the patella in a medial or lateral direction, against the restriction.

Leg and Ankle Joints

The joints of the leg consist of the proximal and distal tibiofibular joints; accessory motions at these joints occur during all ankle and subtalar joint motions. (see Fig. 5.48 and Fig. 5.57 A) The complex mechanics of the leg, foot, and ankle in weight-bearing and nonweight-bearing conditions are described in Chapter 22.

Tibiofibular Joints

Proximal Tibiofibular Articulation: Anterior (Ventral) Glide (Fig. 5.55)

Indications

To increase movement of the fibular head; to reposition a posteriorly subluxed head.

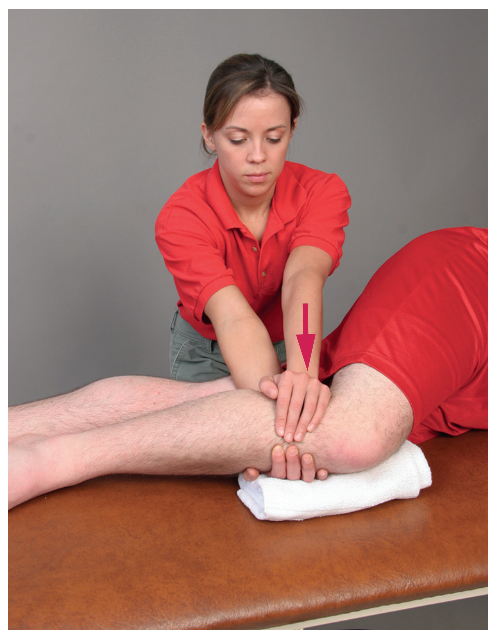

FIGURE 5.55 Proximal tibiofibular joint: anterior glide.

Patient Position

- Side-lying, with the trunk and hips rotated partially toward prone.
- The top leg is flexed forward so the knee and lower leg are resting on the table or supported on a pillow.

Therapist Position and Hand Placement

- Stand behind the patient, placing one of your hands under the tibia to stabilize it.
- Place the base of your other hand posterior to the head of the fibula, wrapping your fingers anteriorly.

Mobilizing Force

Apply the force through the heel of your hand against the posterior aspect of the fibular head, in an anterior-lateral direction.

Distal Tibiofibular Articulation: Anterior (Ventral) or Posterior (Dorsal) Glide (Fig. 5.56)

Indication

To increase mobility of the mortise when it is restricting ankle dorsiflexion.

FIGURE 5.56 Distal tibiofibular articulation: posterior glide.

Patient Position

Supine or prone.

Hand Placement

Working from the end of the table, place the fingers of the more medial hand under the tibia and the thumb over the tibia to stabilize it. Place the base of your other hand over the lateral malleolus, with the fingers underneath.

Mobilizing Force

Press against the fibula in an anterior direction when prone and in a posterior direction when supine.

Talocrural Joint (Upper Ankle Joint) (Fig. 5.57)

The convex talus articulates with the concave mortise made up of the tibia and fibula.

Resting position. The resting position is 10° plantarflexion.

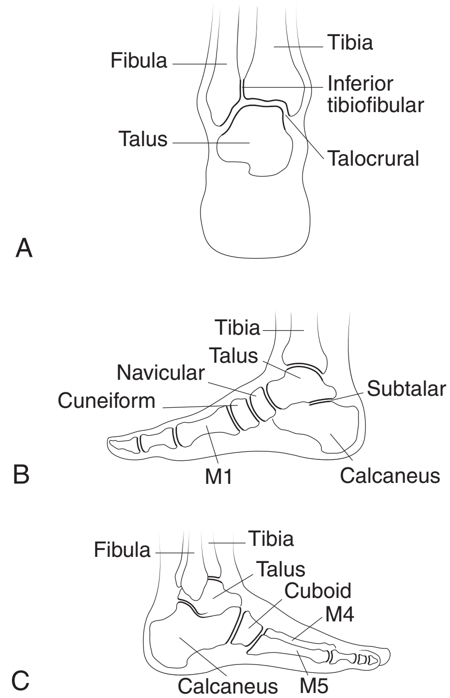

FIGURE 5.57 (A) Anterior view of the bones and joints of the lower leg and ankle. **(B)** Medial view. **(C)** Lateral view of the bones and joint relationships of the ankle and foot.

Treatment plane. The treatment plane is in the mortise, in an anterior-posterior direction with respect to the leg.

Stabilization. The tibia is strapped or held against the table.

Talocrural Distraction (Fig. 5.58) VIDEO 5.12

Indications

Testing; initial treatment; pain control; general mobility.

Patient Position

Supine, with the lower extremity extended. Begin with the ankle in resting position. Progress to the end of the available range of dorsiflexion or plantarflexion.

FIGURE 5.58 Talocrural joint: distraction.

Therapist Position and Hand Placement

- Stand at the end of the table; wrap the fingers of both hands over the dorsum of the patient's foot, just distal to the mortise.
- Place your thumbs on the plantar surface of the foot to hold it in resting position.

Mobilizing Force

Pull the foot along the long axis of the leg in a distal direction by leaning backward.

Talocrural Dorsal (Posterior) Glide (Fig. 5.59)

Indication

To increase dorsiflexion.

FIGURE 5.59 Talocrural joint: posterior glide.

Patient Position

Supine, with the leg supported on the table and the heel over the edge.

Therapist Position and Hand Placement

- Stand to the side of the patient.
- Stabilize the leg with your cranial hand or use a belt to secure the leg to the table.
- Place the palmar aspect of the web space of your other hand over the talus just distal to the mortise.
- Wrap your fingers and thumb around the foot to maintain the ankle in resting position. Grade I distraction force is applied in a caudal direction.

Mobilizing Force

Glide the talus posteriorly with respect to the tibia by pushing against the talus.

Talocrural Ventral (Anterior) Glide (Fig. 5.60)

Indication

To increase plantarflexion.

Patient Position

Prone, with the foot over the edge of the table.

FIGURE 5.60 Talocrural joint: anterior glide.

Therapist Position and Hand Placement

- Working from the end of the table, place your lateral hand across the dorsum of the foot to apply a grade I distraction.
- Place the web space of your other hand just distal to the mortise on the posterior aspect of the talus and calcaneus.

Mobilizing Force

Push against the calcaneus in an anterior direction (with respect to the tibia); this glides the talus anteriorly.

Alternate Position

- Patient is supine. Stabilize the distal leg anterior to the mortise with your proximal hand.
- The distal hand cups under the calcaneus.
- When you pull against the calcaneus in an anterior direction, the talus glides anteriorly.

Subtalar Joint (Talocalcaneal), Posterior Compartment

The articulations between the calcaneus and talus are divided by the tarsal canal. The complex mechanics of these separate articulations are described in Chapter 22. Only mobilization of the posterior compartment is described here. The calcaneus is convex, articulating with a concave talus in the posterior compartment.

Resting position. The resting position is midway between inversion and eversion.

Treatment plane. The treatment plane is in the talus, parallel to the sole of the foot.

Stabilization. Dorsiflexion of the ankle stabilizes the talus. Alternatively, the talus is stabilized with one of your hands.

Subtalar Distraction (Fig. 5.61) VIDEO 5.13

Indications

Testing; initial treatment; pain control; general mobility for inversion/eversion.

FIGURE 5.61 Subtalar (talocalcaneal) joint: distraction.

Patient and Therapist Positions and Hand Placement

- The patient is placed in a supine position, with the leg supported on the table and heel over the edge.
- The hip is externally rotated so the talocrural joint can be stabilized in dorsiflexion with pressure from your thigh against the plantar surface of the patient's forefoot.
- The distal hand grasps around the calcaneus from the posterior aspect of the foot. The other hand fixes the talus and malleoli against the table.

Mobilizing Force

Pull the calcaneus distally with respect to the long axis of the leg.

Subtalar Medial Glide or Lateral Glide (Fig. 5.62)

Indications

Medial glide to increase eversion; lateral glide to increase inversion.

Patient Position

The patient is side-lying or prone, with the leg supported on the table or with a towel roll.

Therapist Position and Hand Placement

- Align your shoulder and arm parallel to the bottom of the foot.
- Stabilize the talus with your proximal hand.
- Place the base of the distal hand on the side of the calcaneus medially to cause a lateral glide and laterally to cause a medial glide.
- Wrap the fingers around the plantar surface.

Mobilizing Force

Apply a grade I distraction force in a caudal direction, then push with the base of your hand against the side of the calcaneus parallel to the plantar surface of the heel.

Alternate Position

Same as the position for distraction, moving the calcaneus in the medial or a lateral direction with the base of the hand.

Intertarsal and Tarsometatarsal Joints

When moving in a dorsal-plantar direction with respect to the foot, all of the articulating surfaces are concave and convex in the same direction. For example, the proximal articulating surface is convex, and the distal articulating surface is concave. The technique for mobilizing each joint is the same. The hand placement is adjusted to stabilize the proximal bone partner so the distal bone partner can be moved.

FIGURE 5.62 ubtalar joint: lateral glide. **(A)** prone. **(B)** side-lying.

Intertarsal and Tarsometatarsal Plantar Glide (Fig. 5.63)

Indication

To increase plantarflexion accessory motions (necessary for supination).

Patient Position

Supine, with hip and knee flexed, or sitting, with knee flexed over the edge of the table and heel resting on your lap.

FIGURE 5.63 Plantar glide of a distal tarsal bone on a stabilized proximal bone. Shown is the cuneiform bone on the navicular.

Stabilization and Hand Placement

- Fixate the more proximal bone with your index finger on the plantar surface of the bone.
- To mobilize the tarsal joints along the medial aspect of the foot, position yourself on the lateral side of the foot. Place the proximal hand on the dorsum of the foot with the fingers pointing medially, so the index finger can be wrapped around and placed under the bone to be stabilized.
- Place your thenar eminence of the distal hand over the dorsal surface of the bone to be moved and wrap the fingers around the plantar surface.
- To mobilize the lateral tarsal joints, position yourself on the medial side of the foot, point your fingers laterally, and position your hands around the bones as just described.

Mobilizing Force

Push the distal bone in a plantar direction from the dorsum of the foot.

Intertarsal and Tarsometatarsal Dorsal Glide (Fig. 5.64)

Indication

To increase the dorsal gliding accessory motion (necessary for pronation).

FIGURE 5.64 Dorsal gliding of a distal tarsal on a proximal tarsal. Shown is the cuboid bone on the calcaneus.

Patient Position

Prone, with knee flexed.

Stabilization and Hand Placement

- Fixate the more proximal bone.
- To mobilize the lateral tarsal joints (e.g., cuboid on calcaneus), position yourself on the medial side of the patient's leg and wrap your fingers around the lateral side of the foot (as in Fig. 5.64).
- To mobilize the medial bones (e.g., navicular on talus), position yourself on the lateral side of the patient's leg and wrap your fingers around the medial aspect of the foot.
- Place your second metacarpophalangeal joint against the bone to be moved.

Mobilizing Force

Push from the plantar surface in a dorsal direction.

Alternate Technique

Same position and hand placements as for plantar glides, except the distal bone is stabilized and the proximal bone is forced in a plantar direction. This is a relative motion of the distal bone moving in a dorsal direction.

Intermetatarsal, Metatarsophalangeal, and Interphalangeal Joints

The intermetatarsal, metatarsophalangeal, and interphalangeal joints of the toes are stabilized and mobilized in the same manner as the fingers. In each case, the articulating surface of the proximal bone is convex, and the articulating surface of the distal bone is concave. It is easiest to stabilize the proximal bone and glide the surface of the distal bone either plantarward for flexion, dorsalward for extension, and medially or laterally for adduction and abduction.

Independent Learning Activities

Critical Thinking and Discussion

1. An individual is immobilized in a cast for 4 to 6 weeks following a fracture. In general, what structures lose their elasticity, and what restrictions do you feel when testing range of motion, joint play, and flexibility?
2. Describe the normal arthrokinematic relationships for the extremity joints and define the location of the treatment plane for each joint.
3. Using the information from activity 1, define a specific fracture, such as a Colle's fracture of the distal forearm. Identify what techniques are necessary to gain joint mobility and range of motion in the related joints such as the wrist, forearm, and elbow joints, connective tissues, and muscles. Practice using each of the techniques.
4. Explain the rationale for using passive joint techniques to treat patients with limitations because of pain and muscle guarding or to treat patients with restricted capsular or ligamentous tissue. What is the difference in the way the techniques are applied in each case?
5. Describe how joint mobilization techniques fit into the total plan of therapeutic intervention for patients with impaired joint mobility.
6. Explain the difference between passive joint mobilization techniques and mobilization with movement techniques.

Laboratory Practice

With a partner, practice mobilizing each joint in the upper and lower extremities.

PRECAUTION: Do not practice on an individual with a hypermobile or unstable joint.

1. Begin with the joint in its resting position and apply distraction techniques at each intensity (sustained grades I, II, and III) to develop a feel for "very gentle," "taking up the slack," and "stretch." Do not apply a vigorous stretch to someone with a normal joint. Be sure to use appropriate stabilization.
2. With the joint in its resting position, practice all appropriate glides for that joint. Be sure to use a grade I distraction with each gliding technique. Vary the techniques between sustained and oscillation.
3. Practice progressing each technique by taking the joint to a point that you determine to be the "end of the range" and:
   - Apply a distraction technique with the extremity in that position.
   - Apply the appropriate glide at that range (be sure to apply a grade I distraction with each glide).
   - Add rotation (e.g., external rotation for shoulder abduction) and then apply the appropriate glide.

CHAPTER

6

Resistance Exercise for Impaired Muscle Performance

Muscle performance refers to the capacity of a muscle to do work (force × distance).[11] Despite the simplicity of the definition, muscle performance is a complex component of functional movement and is influenced by all of the body systems. Factors that affect muscle performance include the morphological qualities of muscle; neurological, biochemical, and biomechanical influences; and metabolic, cardiovascular, respiratory, cognitive, and emotional function. For a person to anticipate, respond to, and control the forces applied to the body and carry out the physical demands of everyday life in a safe and efficient manner, the body's muscles must be able to produce, sustain, and regulate muscle tension to meet these demands.

The key elements of muscle performance are *strength*, *power*, and *endurance*.[11] If any one or more of these areas of muscle performance is impaired, activity limitations (functional limitations) and participation restriction (disability) or increased risk of dysfunction may ensue. Many factors, such as injury, disease, immobilization, disuse, and inactivity, may result in impaired muscle performance, leading to weakness and muscle atrophy. When deficits in muscle performance place a person at risk for injury or hinder function, the use of resistance exercise is an appropriate therapeutic intervention to improve the integrated use of strength, power, and muscular endurance during functional movements, to reduce the risk of injury or re-injury, and to enhance physical performance.

Resistance exercise is any form of active exercise in which dynamic or static muscle contraction is resisted by an outside force applied manually or mechanically.[103,248] Resistance exercise, also referred to as *resistance training*,[8,9,167] is an essential element of rehabilitation programs for persons with impaired function and an integral component of conditioning programs for those who wish to promote or maintain health and physical well-being, potentially enhance performance of motor skills, and reduce the risk of injury and disease.[8,9,242]

A comprehensive examination and evaluation of a patient or client are the foundations on which a therapist determines whether a program of resistance exercise is warranted and can improve a person's current level of function or prevent potential dysfunction. Many factors influence how appropriate, effective, or safe resistance training is and how the exercises are designed, implemented, and progressed. Factors, such as the underlying pathology; the extent and severity of muscle performance impairments; the presence of other deficits; the stage of tissue healing after injury or surgery; and a patient's or client's age, overall level of fitness, and ability to cooperate and learn, all must be considered. Once a program of resistance exercise is developed and prescribed to meet specific functional goals and outcomes, direct intervention by a therapist initially to implement the exercise program or to begin to teach and supervise the prescribed exercises for a smooth transition to an independent, home-based program is imperative.

This chapter provides a foundation of information on resistance exercise, identifies the determinants of resistance training programs, summarizes the principles and guidelines for application of manual and mechanical resistance exercise, and explores a variety of regimens for resistance training. It also addresses the scientific evidence, when available, of the relationship between improvements in muscle performance and enhanced functional abilities. The specific techniques described and illustrated in this chapter focus on manual resistance exercise for the extremities, primarily used during the early phase of rehabilitation. Additional exercises performed independently by a patient or client using resistance equipment are described and illustrated in Chapters 17 through 23. The use of resistance exercise for spinal conditions is presented in Chapter 16.

Muscle Performance and Resistance Exercise: Definitions and Guiding Principles

The three elements of muscle performance[11]—strength, power, and endurance—can be enhanced by some form of resistance exercise. To what extent each of these elements is altered by exercise depends on how the principles of resistance training are applied and how factors such as the intensity, frequency, and duration of exercise are manipulated. Because the physical demands of work, recreation, and everyday living usually involve all three aspects of muscle performance, most resistance training programs seek to achieve a balance of strength, power, and muscular endurance to suit an individual's needs and goals. In addition to having a positive impact on muscle performance, resistance training can produce many other benefits.[8-10] These potential benefits are listed in Box 6.1. After a brief description of the three elements of muscle performance, guiding principles of exercise prescription and training are discussed in this section.

Strength, Power, and Endurance

Strength

Muscle strength is a broad term that refers to the ability of contractile tissue to produce tension and a resultant force based on the demands placed on the muscle.[182,192,210] More specifically, muscle strength is the greatest measurable force that can be exerted by a muscle or muscle group to overcome resistance during a *single* maximum effort.[11] *Functional strength* relates to the ability of the neuromuscular system to produce, reduce, or control forces, contemplated or imposed, during functional activities, in a smooth, coordinated manner.[42,219] Insufficient muscular strength can contribute to major functional losses of even the most basic activities of daily living.

Strength training. The development of muscle strength is an integral component of most rehabilitation or conditioning

BOX 6.1 Potential Benefits of Resistance Exercise

- Enhanced muscle performance: restoration, improvement or maintenance of muscle strength, power, and endurance
- Increased strength of connective tissues: tendons, ligaments, intramuscular connective tissue
- Greater bone mineral density or less bone demineralization
- Decreased stress on joints during physical activity
- Reduced risk of soft tissue injury during physical activity
- Possible improvement in capacity to repair and heal damaged soft tissues due to positive impact on tissue remodeling
- Possible improvement in balance
- Enhanced physical performance during daily living, occupational, and recreational activities
- Positive changes in body composition: ↑ lean muscle mass or ↓ body fat
- Enhanced feeling of physical well-being
- Possible improvement in perception of disability and quality of life

programs for individuals of all ages and all ability levels.[8,10,90,168,221] *Strength training* (*strengthening exercise*) is defined as a systematic procedure of a muscle or muscle group lifting, lowering, or controlling heavy loads (resistance) for a relatively low number of repetitions or over a short period of time.[9,31,103] The most common adaptation to heavy resistance exercise is an increase in the maximum force-producing capacity of muscle—that is, an increase in muscle strength, primarily as the result of neural adaptations and an increase in muscle fiber size.[9,10,192]

Power

Muscle power, another aspect of muscle performance, is related to the strength and speed of movement and is defined as the work (force × distance) produced by a muscle per unit of time (force × distance/time).[11,182,192,210] In other words, it is the *rate* of performing work. The rate at which a muscle contracts and produces a resultant force and the relationship of force and velocity are factors that affect muscle power.[31,210] Because work can be produced over a very brief or an extended period of time, power can be expressed by either a single burst of high-intensity activity (such as lifting a heavy piece of luggage onto an overhead rack or performing a high jump) or by repeated bursts of less intense muscle activity (such as climbing a flight of stairs). The terms *anaerobic power* and *aerobic power*, respectively, are sometimes used to differentiate these two aspects of power.[192]

Power training. Many motor skills in our lives are composed of movements that are explosive and involve both strength and speed. Therefore, re-establishing muscle power may be an important priority in a rehabilitation program. Muscle strength is a necessary foundation for developing muscle power. Power can be enhanced by either increasing the work a muscle must perform during a specified period of time or reducing the amount of time required to produce a given force. The greater the intensity of the exercise and the shorter the time period taken to generate force, the greater is the muscle power. For power training regimens, such as *plyometric training* or *stretch-shortening drills*, the speed of movement is the variable that is most often manipulated[293] (see Chapter 23).

Endurance

Endurance is a broad term that refers to the ability to perform low-intensity, repetitive, or sustained activities over a prolonged period of time. *Cardiopulmonary endurance* (*total body endurance*) is associated with repetitive, dynamic motor activities, such as walking, cycling, swimming, or upper extremity ergometry, which involve use of the large muscles of the body.[8,9] This aspect of endurance is explored in Chapter 7.

Muscle endurance (sometimes referred to as *local endurance*) is the ability of a muscle to contract repeatedly against a load (resistance), generate and sustain tension, and resist fatigue over an extended period of time.[8,9,11,234] The term *aerobic power* sometimes is used interchangeably with muscle endurance. Maintenance of balance and proper alignment of the body segments requires sustained control (endurance) by the postural muscles. In fact, almost all daily living tasks require some degree of muscle and cardiopulmonary endurance.

Although strength and muscle endurance, as elements of muscle performance, are associated, they do not always correlate well with each other. Just because a muscle group is strong, it does not preclude the possibility that muscular endurance is impaired. For example, a strong worker has no difficulty lifting a 10-pound object several times, but does the worker have sufficient muscle endurance in the upper extremities and the stabilizing muscles of the trunk and lower extremities to lift 10-pound objects several hundred times during the course of a day's work without excessive fatigue or potential injury?

Endurance training. *Endurance training* (*endurance exercise*) is characterized by having a muscle contract and lift or lower a light load for many repetitions or sustain a muscle contraction for an extended period of time.[9,10,192,210,260] The key parameters of endurance training are low-intensity muscle contractions, a large number of repetitions, and a prolonged time period. Unlike strength training, muscles adapt to endurance training by increases in their oxidative and metabolic capacities, which allows better delivery and use of oxygen. For many patients with impaired muscle performance, endurance training has a more positive impact on improving function than strength training. In addition, using low levels of resistance in an exercise program minimizes adverse forces on joints, produces less irritation to soft tissues, and is more comfortable than heavy resistance exercise.

Overload Principle

Description

The overload principle is a guiding principle of exercise prescription that has been one of the foundations on which the use of resistance exercise to improve muscle performance is based. Simply stated, if muscle performance is to improve, a load that exceeds the metabolic capacity of the muscle must be applied—that is, the muscle must be challenged to perform at a level greater than that to which it is accustomed.[9,10,128,168,192,206] If the demands remain constant after the muscle has adapted, the level of muscle performance can be maintained but not increased.

Application of the Overload Principle

The overload principle focuses on the progressive loading of muscle by manipulating, for example, the intensity or volume of exercise. Intensity of resistance exercise refers to how much weight (resistance) is imposed on the muscle, whereas volume encompasses variables such as repetitions, sets, or frequency of exercise, any one or more of which can be gradually adjusted to increase the demands on the muscle.

- In a strength training program, the amount of resistance applied to the muscle is incrementally and progressively increased.
- For endurance training, more emphasis is placed on increasing the *time* a muscle contraction is sustained or the *number of repetitions* performed than on increasing resistance.

PRECAUTION: To ensure safety, the extent and progression of overload must always be applied in the context of the underlying pathology, age of the patient, stage of tissue healing, fatigue, and the overall abilities and goals of the patient. The muscle and related body systems must be given time to *adapt* to the demands of an increased load or repetitions before the load or number of repetitions is again increased.

SAID Principle

The SAID principle (specific adaptation to imposed demands)[9,192] suggests that a framework of specificity is a necessary foundation on which exercise programs should be built. This principle applies to all body systems and is an extension of Wolff's law (body systems adapt over time to the stresses placed on them). The SAID principle helps therapists determine the exercise prescription and which parameters of exercise should be selected to create specific training effects that best meet specific functional needs and goals.

Specificity of Training

Specificity of training, also referred to as specificity of exercise, is a widely accepted concept suggesting that the adaptive effects of training, such as improvement of strength, power, and endurance, are highly specific to the training method employed.[9,183] Whenever possible, exercises incorporated in a program should mimic the anticipated function. For example, if the desired functional activity requires greater muscular endurance than strength, the intensity and duration of exercises should be geared to improve muscular endurance.

Specificity of training also should be considered with respect to mode (type) and velocity of exercise[24,80,205,225] as well as patient or limb position (joint angle)[161,162,285] and the movement pattern during exercise. For example, if the desired functional outcome is the ability to ascend and descend stairs, exercise should be performed eccentrically and concentrically in a weight-bearing pattern and progressed to the desired speed. Regardless of the simplicity or complexity of the motor task to be learned, task-specific practice always must be emphasized. It has been suggested that the basis of specificity of training is related to morphological and metabolic changes in muscle as well as neural adaptations to the training stimulus associated with motor learning.[218]

Transfer of Training

In contrast to the SAID principle, carryover of training effects from one variation of exercise or task to another also has been reported. This phenomenon is called transfer of training, overflow, or a cross-training effect. Transfer of training has been reported to occur on a very limited basis with respect to the velocity of training[143,273] and the type or mode of exercise.[80] Furthermore, it has been suggested that a cross-training effect can occur from an exercised limb to a nonexercised, contralateral limb in a resistance training program.[283,284]

A program of exercises designed to develop muscle strength also has been shown to improve muscular endurance at least moderately. In contrast, endurance training has little to no cross-training effect on strength.[9,18,103] Strength training at one speed of exercise has been shown to provide some improvement in strength at higher or lower speeds of exercise. However, the overflow effects are substantially less than the training effects resulting from specificity of training.

Despite the evidence that a small degree of transfer of training does occur in a resistance exercise program, most studies support the importance of designing an exercise program that most closely replicates the desired functional activities. As many variables as possible in the exercise program should match the requirements and demands placed on a patient during specific functional activities.

Reversibility Principle

Adaptive changes in the body's systems, such as increased strength or endurance, in response to a resistance exercise program are transient unless training-induced improvements are regularly used for functional activities or unless an individual participates in a maintenance program of resistance exercises.[8,9,46,89,192]

Detraining, reflected by a reduction in muscle performance, begins within a week or two after the cessation of resistance exercises and continues until training effects are lost.[9,89,167,207] For this reason, it is imperative that gains in strength and endurance are incorporated into daily activities as early as possible in a rehabilitation program. It is also

advisable for patients to participate in a maintenance program of resistance exercises as an integral component of a lifelong fitness program.

Skeletal Muscle Function and Adaptation to Resistance Exercise

Knowledge of the factors that influence the force-producing capacity of normal muscle during an active contraction is fundamental to understanding how the neuromuscular system adapts as the result of resistance training. This knowledge, in turn, provides a basis on which a therapist is able to make sound clinical decisions when designing resistance exercise programs for patients with weakness and functional limitations as the result of injury or disease or to enhance physical performance and prevent or reduce the risk of injury in healthy individuals.

Factors that Influence Tension Generation in Normal Skeletal Muscle

NOTE: For a brief review of the structure of skeletal muscle, refer to Chapter 4 of this textbook. For in-depth information on muscle structure and function, numerous resources are available.[182,183,192,210]

Diverse but interrelated factors affect the tension-generating capacity of *normal* skeletal muscle necessary to control the body and perform motor tasks. Determinants and correlates include morphological, biomechanical, neurological, metabolic, and biochemical factors. All contribute to the *magnitude*, *duration*, and *speed* of force production as well as how resistant or susceptible a muscle is to fatigue. Properties of muscle itself and as key neural factors and their impact on tension generation during an active muscle contraction are summarized in Table 6.1.[9,182,183,192,210]

Additional factors—such as the energy stores available to muscle, the influence of fatigue and recovery from exercise, and a person's age, gender, and psychological/cognitive status, as well as many other factors—affect a muscle's ability to develop and sustain tension. A therapist must recognize that these factors affect a patient's performance during exercise as well as the potential outcomes of the exercise program.

Energy Stores and Blood Supply

Muscle needs adequate sources of energy (fuel) to contract, generate tension, and resist fatigue. The predominant fiber type found in the muscle and the adequacy of blood supply, which transports oxygen and nutrients to muscle and removes waste products, affect the tension-producing capacity of a

TABLE 6.1 Determinants and Correlates that Affect Tension Generation of Skeletal Muscle

Factor	Influence
Cross-section and size of the muscle (includes muscle fiber number and size)	The larger the muscle diameter, the greater its tension-producing capacity.
Muscle architecture—fiber arrangement and fiber length (also relates to cross-sectional diameter of the muscle)	Short fibers with pinnate and multipinnate design in high force-producing muscles (ex. quadriceps, gastrocnemius, deltoid, biceps brachii).
	Long, parallel design in muscles with high rate of shortening but less force production (ex. sartorius, lumbricals).
Fiber-type distribution of muscle—type I (tonic, slow-twitch) and type IIA & IIB (phasic, fast-twitch)	High percentage of type I fibers—low force production, slow rate of maximum force development, resistant to fatigue.
	High percentage of type IIA and IIB fibers—rapid high force production; rapid fatigue.
Length-tension relationship of muscle at time of contraction	Muscle produces greatest tension when it is near or at the physiological resting length at the time of contraction.
Recruitment of motor units	The greater the number and synchronization of motor units firing, the greater the force production.
Frequency of firing of motor units	The higher the frequency of firing, the greater the tension.
Type of muscle contraction	Force output from greatest to least—eccentric, isometric, concentric muscle contraction.
Speed of muscle contraction (force-velocity relationship)	Concentric contraction: ↑ speed → ↓ tension. Eccentric contraction: ↑ speed → ↑ tension.

muscle and its resistance to fatigue. The three main energy systems (ATP-PC system, anaerobic/glycolytic/lactic acid system, aerobic system) are reviewed in Chapter 7.

Fatigue

Fatigue is a complex phenomenon that affects muscle performance and must be considered in a resistance exercise program. Fatigue has a variety of definitions that are based on the type of fatigue being addressed.

Muscle (local) fatigue. Most relevant to resistance exercise is the phenomenon of skeletal muscle fatigue. Muscle (local) fatigue—the diminished response of muscle to a repeated stimulus—is reflected in a progressive decrement in the amplitude of motor unit potentials.[183,192] This occurs during exercise when a muscle repeatedly contracts statically or dynamically against an imposed load.

This *acute* physiological response to exercise is *normal* and *reversible.* It is characterized by a gradual decline in the force-producing capacity of the neuromuscular system—that is, a *temporary* state of exhaustion (failure), leading to a decrease in muscle strength.[23,56,183,253]

The diminished response of the muscle is caused by a complex combination of factors, which include disturbances in the contractile mechanism of the muscle itself (associated with a decrease in energy stores, insufficient oxygen, reduced sensitivity and availability of intracellular calcium, and a build-up of H^+) and perhaps reduced excitability at the neuromuscular junction or inhibitory (protective) influences from the central nervous system.[183,192,210]

The fiber-type distribution of a muscle, which can be divided into two broad categories (type I and type II), affects how resistant it is to fatigue.[183,192,210] Type II (phasic, fast-twitch) muscle fibers are further divided into two additional classifications (types IIA and IIB) based on contractile and fatigue characteristics. Some resources subdivide type II fibers into three classifications.[239] In general, type II fibers generate a great amount of tension within a short period of time, with type IIB being geared toward anaerobic metabolic activity and having a tendency to fatigue more quickly than type IIA fibers. Type I (tonic, slow-twitch) muscle fibers generate a low level of muscle tension but can sustain the contraction for a long time. These fibers are geared toward aerobic metabolism, as are type IIA fibers. However, type I fibers are more resistant to fatigue than type IIA. Table 6.2 compares the characteristics of muscle fiber types.[9,182,183,210]

Because different muscles are composed of varying proportions of tonic and phasic fibers, their function becomes specialized. For example, a heavy distribution of type I (slow twitch, tonic) fibers is found in postural muscles, which allows muscles, such as the soleus, to sustain a low level of tension for extended periods of time to hold the body erect against gravity or stabilize against repetitive loads. On the other end of the fatigue spectrum, muscles with a large distribution of type IIB (fast twitch, phasic) fibers, such as the gastrocnemius or biceps brachii, produce a great burst of tension to enable a person to lift the entire body weight or to lift, lower, push, or pull a heavy load but fatigue quickly.

TABLE 6.2 Muscle Fiber Types and Resistance to Fatigue

Characteristics	Type I	Type IIA	Type IIB
Resistance to fatigue	High	Intermediate	Low
Capillary density	High	High	Low
Energy system	Aerobic	Aerobic	Anerobic
Diameter	Small	Intermediate	Large
Twitch rate	Slow	Fast	Fast
Maximum muscle-shortening velocity	Slow	Fast	Fast

Clinical signs of muscular fatigue during exercise are summarized in Box 6.2.[192,210] When these signs and symptoms develop during resistance exercise, it is time to decrease the load on the exercising muscle or stop the exercise and shift to another muscle group to allow time for the fatigued muscle to rest and recover.

Cardiopulmonary (general) fatigue. This type of fatigue is the diminished response of an individual (the entire body) as the result of prolonged physical activity, such as walking, jogging, cycling, or repetitive lifting or digging. It is related to the body's ability to use oxygen efficiently. Cardiopulmonary fatigue associated with endurance training is probably caused by a combination of the following factors.[23,114]

- Decrease in blood sugar (glucose) levels.
- Decrease in glycogen stores in muscle and liver.
- Depletion of potassium, especially in the elderly patient.

BOX 6.2 Signs and Symptoms of Muscle Fatigue

- An uncomfortable sensation in the muscle, even pain and cramping
- Tremulousness in the contracting muscle
- An unintentional slowing of movement with successive repetitions of an exercise
- Active movements: jerky, not smooth
- Inability to complete the movement pattern through the full range of available motion during dynamic exercise against the same level of resistance
- Use of substitute motions—that is, incorrect movement patterns—to complete the movement pattern
- Inability to continue low-intensity physical activity
- Decline in peak torque during isokinetic testing

Threshold for fatigue. Threshold for fatigue is the level of exercise that cannot be sustained indefinitely.[23] A patient's threshold for fatigue could be noted as the length of time a contraction is maintained or the number of repetitions of an exercise that initially can be performed. This sets a baseline from which adaptive changes in physical performance can be measured.

Factors that influence fatigue. Factors that influence fatigue are diverse. A patient's health status, diet, or lifestyle (sedentary or active) all influence fatigue. In patients with neuromuscular, cardiopulmonary, inflammatory, cancer-related, or psychological disorders, the onset of fatigue is often abnormal.[4,56,98] For instance, it may occur abruptly, more rapidly, or at predictable intervals.

It is advisable for a therapist to become familiar with the patterns of fatigue associated with different diseases and medications. In multiple sclerosis, for example, the patient usually awakens rested and functions well during the early morning. By mid-afternoon, however, the patient reaches a peak of fatigue and becomes notably weak. Then, by early evening, the fatigue diminishes and strength returns. Patients with cardiac, peripheral vascular, and pulmonary diseases, as well as patients with cancer undergoing chemotherapy or radiation therapy, all have deficits that compromise the oxygen transport system. Therefore, these patients fatigue more readily and require a longer period of time for recovery from exercise.[4,98]

Environmental factors, such as outside or room temperature, air quality, and altitude, also influence how quickly the onset of fatigue occurs and how much time is required for recovery from exercise.[169,192]

Recovery from Exercise

Adequate time for recovery from fatiguing exercise must be built into every resistance exercise program. This applies to both intrasession and intersession recovery. After vigorous exercise, the body must be given time to restore itself to a state that existed prior to the exhaustive exercise. Recovery from acute exercise, in which the force-producing capacity of muscle returns to 90% to 95% of the pre-exercise capacity, usually takes 3 to 4 minutes, with the greatest proportion of recovery occurring in the first minute.[51,244]

During recovery oxygen and energy stores are replenished quickly in muscles. Lactic acid is removed from skeletal muscle and blood within approximately 1 hour after exercise, and glycogen is replaced over several days.

FOCUS ON EVIDENCE

Studies over several decades have demonstrated that if light exercise is performed during the recovery period (*active recovery*), recovery from exercise occurs more rapidly than with total rest (*passive recovery*).[28,51,113,244] Faster recovery with light exercise is probably the result of neural as well as circulatory influences.[51,244]

CLINICAL TIP

Only if a patient is allowed adequate time to recover from fatigue after each exercise session does muscle performance (strength, power, or endurance) improve over time.[28,113] If a sufficient rest interval is not a recurring component of a resistance exercise program, a patient's performance plateaus or deteriorates. Evidence of overtraining or overwork weakness may become apparent (see additional discussion in a later section of this chapter). It has also been shown that fatigued muscles are more susceptible to acute strains.[190]

Age

Muscle performance changes throughout the life span. Whether the goal of a resistance training program is to remediate impairments and activity limitations (functional limitations) or enhance fitness and performance of physical activities, an understanding of "typical" changes in muscle performance and response to exercise during each phase of life from early childhood through the advanced years of life is necessary to prescribe effective, safe resistance exercises for individuals of all ages. Key aspects of how muscle performance changes throughout life are discussed in this section and summarized in Box 6.3.

Early Childhood and Preadolescence

In absolute terms, muscle performance (specifically strength), which in part is related to the development of muscle mass, increases *linearly* with chronological age in both boys and girls from birth through early and middle childhood to puberty.[191,261,290] Muscle endurance also increases linearly during the childhood years.[290] Muscle fiber number is essentially determined prior to or shortly after birth,[241] although there is speculation that fiber number may continue to increase into early childhood.[290] The rate of fiber growth (increase in cross-sectional area) is relatively consistent from birth to puberty. Change in fiber type distribution is relatively complete by the age of 1, shifting from a predominance of type II fibers to a more balanced distribution of type I and type II fibers.[290]

Throughout childhood, boys have slightly greater absolute and relative muscle mass (kilograms of muscle per kilogram of body weight) than girls, with boys approximately 10% stronger than girls from early childhood to puberty.[191] This difference may be associated with differences in relative muscle mass, although social expectations, especially by midchildhood, also may contribute to the observed difference in muscle strength.

It is well established that an appropriately designed resistance exercise program can improve muscle strength in children above and beyond gains attributable to typical growth and development. Furthermore, training-induced strength gains in prepubescent children occur primarily as the result of neuromuscular adaptation—that is, without a significant increase in muscle mass.[22,91] Reviews of the literature[90,92] have cited many studies that support these findings. However, there

BOX 6.3 Summary of Age-Related Changes in Muscle and Muscle Performance Through the Life Span

Infancy, Early Childhood, and Preadolescence
- At birth, muscle accounts for about 25% of body weight.
- Total number of muscle fibers is established prior to birth or early in infancy.
- Postnatal changes in distribution of type I and type II fibers in muscle are relatively complete by the end of the first year of life.
- Muscle fiber size and muscle mass increase linearly from infancy to puberty.
- Muscle strength and muscle endurance increase linearly with chronological age in boys and girls throughout childhood until puberty.
- Muscle mass (absolute and relative) and muscle strength is just slightly greater (approximately 10%) in boys than girls from early childhood to puberty.
- Training-induced strength gains occur equally in both sexes during childhood *without* evidence of hypertrophy (increased muscle mass) until puberty.

Puberty
- Rapid acceleration in muscle fiber size and muscle mass, especially in boys. During puberty, muscle mass increases more than 30% per year.
- Rapid increase in muscle strength in both sexes.
- Marked difference in strength levels develops in boys and girls.
- In boys, muscle mass and body height and weight peak before muscle strength; in girls, strength peaks before body weight.
- Relative strength gains as the result of resistance training are comparable between the sexes, with significantly greater muscle hypertrophy in boys.

Young and Middle Adulthood
- Muscle mass peaks in women between 16 and 20 years of age; muscle mass in men peaks between 18 and 25 years of age.
- Decreases in muscle mass begin to occur as early as 25 years of age.
- Muscle mass constitutes approximately 40% of total body weight during early adulthood, with men having slightly more muscle mass than women.
- Muscle continues to develop into the second decade, especially in men.
- Muscle strength and endurance reach a peak during the second decade, earlier for women than men.
- By sometime in the third decade, strength declines between 8% and 10% per decade through the fifth or sixth decade.
- Strength and muscle endurance deteriorate less rapidly in physically active versus sedentary adults.
- Improvements in strength and endurance are possible with only a modest increase in physical activity.

Late Adulthood
- Rate of decline of muscle strength accelerates to 15% to 20% per decade during the sixth and seventh decades and increases to 30% per decade thereafter.
- By the eighth decade, as loss of muscle mass continues; skeletal muscle mass has decreased by 50% compared to peak muscle mass during young adulthood.
- Muscle fiber size (cross-sectional area), type I and type II fiber numbers, and the number of alpha motoneurons all decrease. Preferential atrophy of type II muscle fibers occurs.
- Decreases in the speed of muscle contractions and peak power occur.
- Gradual but progressive decrease in endurance and maximum oxygen uptake.
- Loss of flexibility reduces the force-producing capacity of muscle.
- Minimal decline in performance of functional skills occurs during the sixth decade.
- Significant deterioration in functional abilities by the eighth decade is associated with a decline in muscular endurance.
- With a resistance training program, a significant improvement in muscle strength, power, and endurance is possible during late adulthood.
- Evidence of the impact of resistance training on the level of performance of functional motor skills is mixed but promising.

is concern that children who participate in resistance training may be at risk for injuries, such as an epiphyseal fracture or avulsion fracture, because the musculoskeletal system is immature.[22,27,103,266]

The American Academy of Pediatrics,[6] the American College of Sports Medicine (ACSM),[8] and the Centers for Disease Control and Prevention (CDC)[36] support youth participation in resistance training programs if they are designed appropriately, initiated at a reasonable age, and carefully supervised (Fig. 6.1). With this in mind, two important questions need to be addressed: (1) At what point during childhood is a resistance training program appropriate? and (2) What constitutes a safe training program?

There is general consensus that during the toddler, preschool, and even the early elementary school years, free play and organized but age-appropriate physical activities are effective methods to promote fitness and improve muscle performance, rather than structured resistance training programs. The emphasis throughout most or all of the first decade of life should be on recreation and learning motor skills.[278]

There is lack of agreement, however, on when and under what circumstances resistance training is an appropriate form of exercise for prepubescent children. Although age-appropriate physical activity on a regular basis has been recommended for children for some time,[6,8,36] during the past two or three decades it has become popular for older (preadolescent) boys and girls to participate in sport-specific training programs (including resistance exercises) before, during, and even after the season, in theory, to enhance athletic performance and reduce the risk of sport-related injury. Rehabilitation programs for prepubescent children who sustain injuries during everyday activities also may include resistance exercises. Consequently, an understanding of the effects of exercise in

FIGURE 6.1 Resistance training, if initiated during the preadolescent years, should be performed using body weight or light weights and carefully supervised.

this age group must be the basis for establishing a safe program with realistic goals.

FOCUS ON EVIDENCE

In the preadolescent age group, many studies have shown that improvements in strength and muscular endurance occur on a relative basis similar to training-induced gains in young adults.[27,92,93,148] It is also important to point out that, although only a few studies have looked at the effects of detraining in children, when training ceases, strength levels gradually return to a pre-training level, as occurs in adults.[89] This suggests that some maintenance level of training could be useful in children as with adults.[90]

Although training-induced gains in strength and muscular endurance are well-documented, there is insufficient evidence to suggest that a structured resistance training program for children (coupled with a general sports conditioning program) reduces injuries or enhances sports performance.[6] However, other health-related benefits of a balanced exercise program have been noted, including increased cardiopulmonary fitness, decreased blood lipids levels, and improved psychological well-being.[22,27,89,148] These findings suggest that participation in a resistance training program during the later childhood (preadolescent) years may, indeed, be of value if the program is performed at an appropriate level (low loads and repetitions), incorporates sufficient rest periods, and is closely supervised.[6,22,90,266]

Adolescence

At puberty, as hormonal levels change, there is rapid acceleration in the development of muscle strength, especially in boys. During this phase of development, typical strength levels become markedly different in boys and girls, which, in part, are caused by hormonal differences between the sexes. Strength in adolescent boys increases about 30% per year between ages 10 and 16, with muscle mass peaking before muscle strength.[34,191] In adolescent girls, peak strength develops before peak weight.[95] Overall, during the adolescent years, muscle mass increases more than 5-fold in boys and approximately 3.5-fold in girls.[34,191] Although most longitudinal studies of growth stop at age 18, strength continues to develop, particularly in males, well into the second and even into the third decade of life.[191]

As with prepubescent children, resistance training during puberty also results in significant strength gains. During puberty, these gains average 30% to 40% above that which is expected as the result of normal growth and maturation.[90] A balanced training program for the adolescent involved in a sport often includes off-season and preseason aerobic conditioning and low-intensity resistance training followed by more vigorous, sport-specific training during the season.[22] The benefits of strength training noted during puberty are similar to those that occur in prepubescent children.[89,93]

Young and Middle Adulthood

Although data on typical strength and endurance levels during the second through the fifth decades of life are more often from studies of men than women, a few generalizations can be made that seem to apply to both sexes.[185] Strength reaches a maximal level earlier in women than men, with women reaching a peak during the second decade and in most men by age 30. Strength then declines approximately 1% per year,[290] or 8% per decade.[107] This decline in strength appears to be minor until about age 50[278] and tends to occur at a later age or slower rate in active adults versus those who are sedentary.[110,290] The potential for improving muscle performance with a resistance training program (Fig. 6.2 A and B) or by participation in even moderately demanding activities several times a week is high during this phase of life. Guidelines for young and middle-aged adults participating in resistance training as part of an overall fitness program have been published by the ACSM[8] and the CDC.[35]

Late Adulthood

The rate of decline in the tension-generating capacity of muscle in most cases accelerates to approximately 15% to 20% per

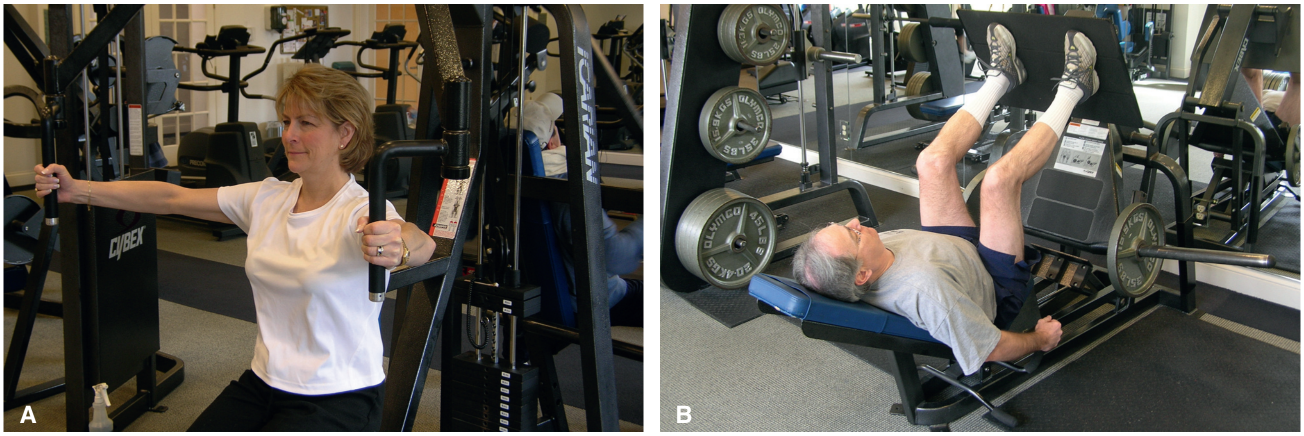

FIGURE 6.2 Conditioning and fitness programs for active young and middle-aged adults include resistance training with a balance of **(A)** upper extremity and **(B)** lower extremity strengthening exercises.

decade in men and women in their sixties and seventies, and it increases to 30% per decade thereafter.[110,185] However, the rate of decline may be significantly less (only 0.3% decrease per year) in elderly men and women who maintain a high level of physical activity.[118] These disparate findings and others suggest that loss of muscle strength during the advanced years may be due, in part, to progressively greater inactivity and disuse.[39] Loss of muscle in the lower extremity and trunk strength and stability during late adulthood—most notably during the seventies, eighties, and beyond—is associated with a gradual deterioration of functional abilities and an increase in the frequency of falling.[39,130]

The decline in muscle strength and endurance in the elderly is associated with many factors in addition to progressive disuse and inactivity. It is difficult to determine if these factors are causes or effects of an age-related decrease in strength. Neuromuscular factors include a decrease in muscle mass (atrophy), decrease in the number of type I and II muscle fibers with a corresponding increase in connective tissue in muscle, a decrease in the cross-sectional size of muscle, selective atrophy of type II fibers, and change in the length-tension relationship of muscle associated with loss of flexibility, more so than deficits in motor unit activation and firing rate.[35,107,141,239,271,278,295] The decline in the number of motor units appears to begin after age 60.[141] All of these changes have an impact on strength and physical performance.

In addition to decreases in muscle strength, declines in the speed of muscle contraction, muscle endurance, and the ability to recover from muscular fatigue occur with advanced age.[141,271] The time needed to produce the same absolute and relative levels of torque output and the time necessary to achieve relaxation after a voluntary contraction are lengthened in the elderly compared to younger adults.[107] Consequently, as velocity of movement declines, so does the ability to generate muscle power during activities that require quick responses, such as rising from a low chair or making balance adjustments to prevent a fall. Deterioration of muscle power with age has a stronger relationship to functional limitations and disability than does muscle strength.[229]

Information on changes in muscle endurance with aging is limited. There is some evidence to suggest that the ability to sustain low-intensity muscular effort also declines with age, in part because of reduced blood supply and capillary density in muscle, decreased mitochondrial density, changes in enzymatic activity level, and decreased glucose transport.[107] As a result, muscle fatigue may tend to occur more readily in the elderly. In the healthy and active (community-dwelling) elderly population, the decline in muscle endurance appears to be minimal well into the seventies.[141]

During the past few decades, as the health care community and the public have become more aware of the benefits of resistance training during late adulthood, a greater number of older adults are participating in fitness programs that include resistance exercises (Fig. 6.3). ACSM and the CDC have published guidelines for resistance training for healthy adults over 60 to 65 years of age (see Box 6.18).[8,37]

FOCUS ON EVIDENCE

A review of the literature indicates that when healthy or frail elderly individuals participate in a resistance training program of appropriate duration and intensity, muscle strength and endurance increase.* Some of these studies have also measured pre-training and post-training levels of functional abilities, such as balance, stair climbing, walking speed, and rising from a chair. The effect of strength and endurance training on functional abilities is promising but still inconclusive, with most but not all[39] investigations demonstrating a positive impact.[3,40,48,97,145,177,227,265]

The disparity of outcomes among investigations underscores the point that resistance training has a direct impact on muscle performance but only an indirect impact on functional performance, a more complex variable. Studies of elderly individuals also have shown that if resistance training is discontinued, detraining gradually occurs; subsequently,

*39,40,47,120,145,177,202,246,263,265,298

FIGURE 6.3 Incorporating resistance training into a fitness program has many benefits for older adults.

strength and functional capabilities deteriorate close to pre-training levels.[46,177]

In summary, evidence indicates that the decline in muscle strength and functional abilities that occurs during late adulthood can be slowed or at least partially reversed with a resistance training program. However, as in other age groups, if these training-induced improvements are to be maintained, some degree of resistance training must be continued.[295]

Psychological and Cognitive Factors

An array of psychological factors can positively or negatively influence muscle performance and how easily, vigorously, or cautiously a person moves. Just as injury and disease adversely affect muscle performance, so can a person's mental status. For example, fear of pain, injury, or re-injury, depression related to physical illness, or impaired attention or memory as the result of age, head injury, or the side effects of medication can adversely affect the ability to develop or sustain sufficient muscle tension for execution or acquisition of functional motor tasks. In contrast, psychological factors can positively influence physical performance.

The principles and methods employed to maximize motor performance and learning as functions of effective patient education are discussed in Chapter 1. These principles and methods should be applied in a resistance training program to develop a requisite level of muscle strength, power, and endurance for functional activities. The following interrelated psychological factors as well as other aspects of motor learning may influence muscle performance and the effectiveness of a resistance training program.

Attention

A patient must be able to focus on a given task (exercise) to learn how to perform it correctly. Attention involves the ability to process relevant data while screening out irrelevant information from the environment and to respond to internal cues from the body. Both are necessary when first learning an exercise and later when carrying out an exercise program independently. Attention to form and technique during resistance training is necessary for patient safety and optimal long-term training effects.

Motivation and Feedback

If a resistance exercise program is to be effective, a patient must be willing to put forth and maintain sufficient effort and adhere to an exercise program over time to improve muscle performance for functional activities. Use of activities that are meaningful and are perceived as having potential usefulness or periodically modifying an exercise routine help maintain a patient's interest in resistance training. Charting or graphing a patient's strength gains, for example, also helps sustain motivation. Incorporating gains in muscle performance into functional activities as early as possible in a resistance exercise program puts improvements in strength to practical use, thereby making those improvements meaningful.

The importance of feedback for learning an exercise or a motor skill is discussed in Chapter 1. In addition, feedback can have a positive impact on a patient's motivation and subsequent adherence to an exercise program. For example, some computerized equipment, such as isokinetic dynamometers, provide visual or auditory signals that let the patient know if each muscle contraction during a particular exercise is in a zone that causes a training effect. Documenting improvements over time, such as the amount of weight (exercise load) used during various exercises or changes in walking distance or speed, also provides positive feedback to sustain a patient's motivation in a resistance exercise program.

Physiological Adaptations to Resistance Exercise

The use of resistance exercise in rehabilitation and conditioning programs has a substantial impact on all systems of the body. Resistance training is equally important for patients with impaired muscle performance and individuals who wish to improve or maintain their level of fitness, enhance performance, or reduce the risk of injury. When body systems are exposed to a greater than usual but appropriate level of resistance in an exercise program, they initially react with a number of *acute* physiological responses and then later adapt—that is, body systems accommodate over time to the newly imposed physical demands.[8,9,192] Training-induced adaptations to resistance exercise, known as *chronic* physiological responses, that affect muscle performance are summarized in Table 6.3 and discussed in this section. Key differences

TABLE 6.3 Physiological Adaptations to Resistance Exercise

Variable	Strength Training Adaptations	Endurance Training Adaptations
Skeletal muscle structure	Muscle fibers hypertrophy: greatest in type IIB fibers. Possible hyperplasia of muscle fibers. Fiber type composition: remodeling of type IIB to type IIA; no change in type I to type II distribution (i.e., no conversion) ↓ or no change in capillary bed density: ↓ in mitochondrial density and volume	Minimal or no muscle fiber hypertrophy ↑ in capillary bed density ↑ in mitochondrial density and volume (↑ number and size)
Neural system	Motor unit recruitment (↑ # of motor units firing) ↑ rate of firing (↓ twitch contraction time) ↑ synchronization of firing	No changes.
Metabolic system and enzymatic activity	↑ ATP and PC storage ↑ myoglobin storage Triglycerides storage: change not known ↑ creatine phosphokinase ↑ myokinase	↑ ATP and PC storage: ↑ myoglobin storage ↑ of stored triglycerides ↑ creatine phosphokinase ↑ myokinase
Body composition	↑ lean (fat-free) body mass; ↓ % body fat	No change in lean body mass; ↓ % body fat
Connective tissue	↑ tensile strength of tendons, ligaments, and connective tissue in muscle ↑ bone mineral density; no change or possible ↑ in bone mass	↑ tensile strength of tendons, ligaments, and connective tissue in muscle ↑ in bone mineralization with land-based, weight-bearing activities

in adaptations from strength training versus endurance training are noted.

Adaptations to overload create changes in muscle performance and, in part, determine the effectiveness of a resistance training program. The time course for these adaptations to occur varies from one individual to another and is dependent on a person's health status and previous level of participation in a resistance exercise program.[10]

Neural Adaptations

It is well accepted that in a resistance training program the initial, rapid gain in the tension-generating capacity of skeletal muscle is attributed largely to neural responses, not adaptive changes in muscle itself.[109,183,203,235] This is reflected by an increase in electromyographic (EMG) activity during the first 4 to 8 weeks of training with little to no evidence of muscle fiber hypertrophy. It is also possible that increased neural activity is the source of additional gains in strength late in a resistance training program even after muscle hypertrophy has reached a plateau.[168,192]

Neural adaptations are attributed to motor learning and improved coordination[109,167,169,192] and include *increased recruitment* in the number of motor units firing as well as an *increased rate and synchronization* of firing.[109,167,225,235] It is speculated that these changes are caused by a decrease in the inhibitory function of the central nervous system (CNS), decreased sensitivity of the Golgi tendon organ (GTO), or changes at the myoneural junction of the motor unit.[109,235]

Skeletal Muscle Adaptations

Hypertrophy

As noted previously, the tension-producing capacity of muscle is directly related to the physiological cross-sectional area of the individual muscle fibers. *Hypertrophy* is an increase in the size (bulk) of an individual muscle fiber caused by an increase in myofibrillar volume.[206,271] After an extended period of moderate- to high-intensity resistance training, usually by 4 to 8 weeks[1,287] but possibly as early as 2 to 3 weeks with very high-intensity resistance training,[255] hypertrophy becomes an increasingly important adaptation that accounts for strength gains in muscle.

Although the mechanism of hypertrophy is complex and the stimulus for growth is not clearly understood, hypertrophy of skeletal muscle appears to be the result of an increase in protein (actin and myosin) synthesis and a decrease in protein degradation. Hypertrophy is also associated with biochemical changes that stimulate uptake of amino acids.[167,192,206,271]

The greatest increases in protein synthesis and, therefore, hypertrophy are associated with high-volume, moderate-resistance exercise performed eccentrically.[167,232] Furthermore, it is the type IIB muscle fibers that appear to increase in size most readily with resistance training.[192,210]

Hyperplasia

Although the topic has been debated for many years and evidence of the phenomenon is sparse, there is some thought that a portion of the increase in muscle size that occurs with heavy resistance training is caused by *hyperplasia*, an increase in the *number* of muscle fibers. It has been suggested that this increase in fiber number, observed in laboratory animals,[116,117] is the result of longitudinal splitting of fibers.[15,139,199] It has been postulated that fiber splitting occurs when individual muscle fibers increase in size to a point at which they are inefficient, then subsequently split to form two distinct fibers.[116]

Critics of the concept of hyperplasia suggest that evidence of fiber splitting actually may be caused by inappropriate tissue preparation in the laboratory.[115] The general opinion in the literature is that hyperplasia either does not occur, or if it does occur to a slight degree, its impact is insignificant.[183,188] In a review article published in the late 1990s, it was the authors' opinion that if hyperplasia is a valid finding, it probably accounts for a very small proportion (less than 5%) of the increase in muscle size that occurs with resistance training.[169]

Muscle Fiber Type Adaptation

As previously mentioned, type II (phasic) muscle fibers preferentially hypertrophy with heavy resistance training. In addition, a substantial degree of plasticity exists in muscle fibers with respect to contractile and metabolic properties.[239] Transformation of type IIB to type IIA is common with endurance training,[239] as well as during the early weeks of heavy resistance training,[255] making the type II fibers more resistant to fatigue. There is some evidence that demonstrates type I to type II fiber type conversion in the denervated limbs of laboratory animals,[216,302] in humans with spinal cord injury, and after an extended period of weightlessness associated with space flight.[239] However, there is little to no evidence of type II to type I conversion under training conditions in rehabilitation or fitness programs.[192,239]

Vascular and Metabolic Adaptations

Adaptations of the cardiovascular and respiratory systems as the result of low-intensity, high-volume resistance training are discussed in Chapter 7. Opposite to what occurs with endurance training, when muscles hypertrophy with high-intensity, low-volume training, capillary bed density actually decreases because of an increase in the number of myofilaments per fiber.[9] Athletes who participate in heavy resistance training actually have fewer capillaries per muscle fiber than endurance athletes and even untrained individuals.[154,269] Other changes associated with metabolism, such as a decrease in mitochondrial density, also occur with high- intensity resistance training.[9,167] This is associated with reduced oxidative capacity of muscle.

Adaptations of Connective Tissues

Although the evidence is limited, it appears that the tensile strength of tendons and ligaments as well as bone increases with resistance training designed to improve the strength or power of muscles.[49,259,303]

Tendons, Ligaments, and Connective Tissue in Muscle

Strength improvement in tendons probably occurs at the musculotendinous junction, whereas increased ligament strength may occur at the ligament-bone interface. It is believed that tendon and ligament tensile strength increases in response to resistance training to support the adaptive strength and size changes in muscle.[303] The connective tissue in muscle (around muscle fibers) also thickens, giving more support to the enlarged fibers.[192] Consequently, strong ligaments and tendons may be less prone to injury. It is also thought that noncontractile soft tissue strength may develop more rapidly with eccentric resistance training than with other types of resistance exercises.[258,259]

Bone

Numerous sources indicate there is a high correlation between muscle strength and the level of physical activity across the life span with bone mineral density.[238] Consequently, physical activities and exercises, particularly those performed in weight-bearing positions, are typically recommended to minimize or prevent age-related bone loss.[226] They are also prescribed to reduce the risk of fractures or improve bone density when osteopenia or osteoporosis is already present.[54,238]

FOCUS ON EVIDENCE

Although the evidence from prospective studies is limited and mixed, resistance exercises performed with adequate intensity and with site-specific loading through weight bearing of the boney area to be tested has been shown to increase or maintain bone mineral density.[156,160,174,198,209] In contrast, a number of studies in young, healthy women[231] and postmenopausal women[228,245] have reported that there was no significant increase in bone mineral density with resistance training. However, the resistance exercises in these studies were not combined with site-specific weight bearing. In addition, the intensity of the weight training programs may not have been high enough to have an impact on bone density.[174,238] The time course of the exercise program also may not have been long enough. It has been suggested that it may take as long as 9 months to a year of exercise for detectable and significant increases in bone mass to occur.[8] In the spine, although studies to date have not shown that resistance training prevents spinal fractures, there is some evidence to suggest that the strength of the back extensors closely correlates with bone mineral density of the spine.[245]

Research continues to determine the most effective forms of exercise to enhance bone density and prevent age-related bone loss and fractures. For additional information on prevention and management of osteoporosis, refer to Chapter 11.

Determinants of Resistance Exercise

Many elements (variables) determine whether a resistance exercise program is appropriate, effective, and safe. This holds true when resistance training is a part of a rehabilitation program for individuals with known or potential impairments in muscle performance or when it is incorporated into a general conditioning program to improve the level of fitness of healthy individuals.

Each of the interrelated elements noted in Box 6.4 and discussed in this section should be addressed to improve one or more aspects of muscle performance and achieve desired functional outcomes. Appropriate *alignment* and *stabilization* are always basic elements of any exercise designed to improve muscle performance. A suitable *dosage* of exercise must also be determined. In resistance training, dosage includes *intensity, volume, frequency,* and *duration* of exercise and *rest interval.* Each factor is a mechanism by which the muscle can be progressively overloaded to improve muscle performance. The *velocity* of exercise and the *mode(type)* of exercise must also be considered. ACSM denotes the key determinants of a resistance training program by the acronym, FITT, which represents frequency, intensity, time, and type of exercise.[8]

Consistent with the SAID principle discussed in the first section of this chapter, these elements of resistance exercise must be specific to the patient's desired functional goals.

BOX 6.4 Determinants of a Resistance Exercise Program

- *Alignment* of segments of the body during exercise
- *Stabilization* of proximal or distal joints to prevent substitution
- *Intensity:* the exercise load (level of resistance)
- *Volume:* the total number of repetitions and sets in an exercise session
- *Exercise order:* the sequence in which muscle groups are exercised during an exercise session
- *Frequency:* the number of exercise sessions per day or per week
- *Rest interval:* time allotted for recuperation between sets and sessions of exercise
- *Duration:* total time frame of a resistance training program
- *Mode* of exercise: type of muscle contraction, position of the patient, form (source) of resistance, arc of movement, or the primary energy system utilized
- *Velocity* of exercise
- *Periodization:* variation of intensity and volume during specific periods of resistance training
- *Integration of exercises into functional activities:* use of resistance exercises that approximate or replicate functional demands

Other factors, such as the underlying cause or causes of the deficits in muscle performance, the extent of impairment, and the patient's age, medical history, mental status, and social situation also affect the design and implementation of a resistance exercise program.

Alignment and Stabilization

Just as correct alignment and effective stabilization are basic elements of manual muscle testing and dynamometry, they are also crucial in resistance exercise. To strengthen a specific muscle or muscle group effectively and avoid substitute motions, appropriate positioning of the body and alignment of a limb or body segment are essential. *Substitute motions* are compensatory movement patterns caused by muscle action of a stronger adjacent agonist or a muscle group that normally serves as a stabilizer (fixator).[158] If the principles of alignment and stabilization for manual muscle testing[137,158] are applied whenever possible during resistance exercise, substitute motions can usually be avoided.

Alignment

Alignment and muscle action. Proper alignment is determined by the direction of muscle fibers and the line of pull of the muscle to be strengthened. The patient or a body segment must be positioned so the direction of movement of a limb or segment of the body replicates the action of the muscle or muscle groups to be strengthened. For example, to strengthen the gluteus medius, the hip must remain slightly extended, not flexed, and the pelvis must be rotated slightly forward as the patient abducts the lower extremity against the applied resistance. If the hip is flexed as the leg abducts, the adjacent tensor fasciae latae becomes the prime mover and is strengthened.

Alignment and gravity. The alignment or position of the patient or the limb with respect to gravity also may be important during some forms of resistance exercises, particularly if body weight or free weights (dumbbells, barbells, cuff weights) are the source of resistance. The patient or limb should be positioned so the muscle being strengthened acts against the resistance of gravity and the weight. This, of course, is contingent on the comfort and mobility of the patient.

Staying with the example of strengthening the gluteus medius, if a cuff weight is placed around the lower leg, the patient must assume the side-lying position so abduction occurs through the full ROM against gravity and the additional resistance of the cuff weight. If the patient rolls toward the supine position, the resistance force is applied primarily to the hip flexors, not the abductors.

Stabilization

Stabilization refers to holding down a body segment or holding the body steady.[158] To maintain appropriate alignment, ensure the correct muscle action and movement pattern, and avoid unwanted substitute motions during resistance exercise,

effective stabilization is imperative. Exercising on a stable surface, such as a firm treatment table, helps hold the body steady. Body weight also may provide a source of stability during exercise, particularly in the horizontal position. It is most common to stabilize the proximal attachment of the muscle being strengthened, but sometimes the distal attachment is stabilized as the muscle contracts.

Stabilization can be achieved externally or internally.

- External stabilization can be applied manually by the therapist or sometimes by the patient with equipment, such as belts and straps, or by a firm support surface, such as the back of a chair or the surface of a treatment table.
- *Internal stabilization* is achieved by an isometric contraction of an adjacent muscle group that does not enter into the movement pattern but holds the body segment of the proximal attachment of the muscle being strengthened firmly in place. For example, when performing a bilateral straight leg raise, the abdominals contract to stabilize the pelvis and lumbar spine as the hip flexors raise the legs. This form of stabilization is effective only if the fixating muscle group is strong enough or not fatigued.

Intensity

The *intensity* of exercise in a resistance training program is the amount of resistance (weight) imposed on the contracting muscle during each repetition of an exercise. The amount of resistance is also referred to as the *exercise load* (training load)—that is, the extent to which the muscle is loaded or how much weight is lifted, lowered, or held.

Remember, consistent with the overload principle, to improve muscle performance the muscle must be loaded to an extent greater than loads usually incurred. One way to overload a muscle progressively is to gradually increase the amount of resistance used in the exercise program.[8,10,103,168,169] The intensity of exercise and the degree to which the muscle is overloaded is also dependent on the volume, frequency, and order of exercise or the length of rest intervals.

Submaximal Versus Maximal Exercise Loads

Many factors, such as the goals and expected functional outcomes of the exercise program; the cause of deficits in muscle performance; the extent of impairment; the stage of healing of injured tissues; the patient's age, general health, and fitness level; and other factors, determine whether the exercise is carried out against submaximal or maximal muscle loading. In general, the level of resistance is often lower in rehabilitation programs for persons with impairments than in conditioning programs for healthy individuals.

Indications for submaximal loading for moderate to low-intensity exercise versus near-maximal or maximal loading for high-intensity exercise are summarized in Table 6.4.

PRECAUTION: The intensity of exercise should never be so great as to cause pain. As the intensity of exercise increases and a patient exerts a maximal or near-maximal effort, cardiovascular risks increase substantially. A patient needs to be continually reminded to incorporate rhythmic breathing into each repetition of an exercise to minimize these risks.

TABLE 6.4 Indications for Low-Intensity Versus High-Intensity Exercise

Submaximal Loading	Near-Maximal or Maximal Loading
In the early stages of soft tissue healing when injured tissues must be protected.	When the goal of exercise is to increase muscle strength and power and possibly increase muscle size.
After prolonged immobilization when the articular cartilage is not able to withstand large compressive forces or when bone demineralization may have occurred, increasing the risk of pathological fracture to evaluate the patient's response to resistance exercise, especially after an extended period of inactivity.	For otherwise healthy adults in the advanced phase of a rehabilitation program after a musculoskeletal injury in preparation for returning to high-demand occupational or recreational activities.
When initially learning an exercise to emphasize the correct form.	In a conditioning program for individuals with no known pathology.
For most children or older adults.	For individuals training for competitive weight lifting or body building.
When the goal of exercise is to improve muscle endurance.	
To warm-up and cool-down prior to and after a session of exercise.	
During slow-velocity isokinetic training to minimize compressive forces on joints.	

Initial Exercise Load (Amount of Resistance) and Documentation of Training Effects

It is always challenging to estimate how much resistance to apply manually or how much weight a patient should use during resistance exercises to improve muscle strength particularly at the beginning of a strengthening program. With manual resistance exercise, the decision is entirely subjective, based on the therapist's judgment during exercise. In an exercise program using mechanical resistance, the determination can be made quantitatively.

Repetition Maximum

One method of measuring the effectiveness of a resistance exercise program and calculating an appropriate exercise load for training is to determine a repetition maximum. This term was first reported decades ago by DeLorme in his investigations of an approach to resistance training called progressive resistive exercise (PRE).[64,65] A *repetition maximum* (RM) is defined as the greatest amount of weight (load) a muscle can move through the full, available ROM with control a specific number of times before fatiguing.

Use of a repetition maximum. There are two main reasons for determining a repetition maximum: (1) to document a baseline measurement of the dynamic strength of a muscle or muscle group against which exercise-induced improvements in strength can be compared; and (2) to identify an initial exercise load (amount of weight) to be used during exercise for a specified number of repetitions. DeLorme reported use of a 1-RM (the greatest amount of weight a subject can move through the available ROM just one time) as the baseline measurement of a subject's maximum effort but used a multiple RM, specifically a 10-RM, (the amount of weight that could be lifted and lowered 10 times through the ROM) during training.[65]

Despite criticism that establishing a 1-RM involves some trial and error, it is a frequently used method for measuring muscle strength in research studies and has been shown to be a safe and reliable measurement tool with healthy young adults and athletes[103,169] as well as active older adults prior to beginning conditioning programs.[202,265,276]

PRECAUTION: Use of a 1-RM as a baseline measurement of dynamic strength is inappropriate for some patient populations because it requires one maximum effort. It is not safe for patients, for example, with joint impairments, patients who are recovering from or who are at risk for soft tissue injury, or patients with known or at risk for osteoporosis or cardiovascular pathology.

CLINICAL TIP

To avoid the trial and error associated with establishing a 1-RM or to eliminate the need for an at-risk patient to exert a single, maximum effort, formulas have been developed and tables have been published[18,140] that enable a therapist to calculate a 1-RM for each muscle group to be strengthened based on the patient performing a greater number of repetitions against a reduced load.

Another practical, time-saving way to establish a baseline RM as an index for assessing dynamic strength for a particular muscle group is for a therapist to select a specific amount of resistance (weight) and document how many repetitions can be completed through the full range before the muscle begins to fatigue. If six repetitions, for example, were completed, the baseline resistance would be based on a 6-RM. Remember, a sign of fatigue is the inability to complete the full, available ROM against the applied resistance.

Alternative Methods of Determining Baseline Strength or an Initial Exercise Load

Cable tensiometry[192] and isokinetic or handheld dynamometry[57] are alternatives to a repetition maximum for establishing a baseline measurement of dynamic or static strength. A percentage of body weight also has been proposed to estimate how much resistance (load) should be used in a strength training program.[236] Some examples for several exercises are noted in Box 6.5. The percentages indicated are meant as guidelines for the advanced stage of rehabilitation and are based on 10 repetitions of each exercise at the beginning of an exercise program. Percentages vary for different muscle groups.

When a maximum effort is inappropriate, the level of perceived loading, as measured by the Borg CR 10 Scale, has been shown to be a useful tool in estimating an appropriate level of resistance and sufficient exercise intensity for muscle strengthening.[13]

Training Zone

After establishing the baseline RM, the amount of resistance (exercise load) to be used at the initiation of resistance training often is calculated as a *percentage* of a 1-RM for a particular muscle group. At the beginning of an exercise program the percentage necessary to achieve training-induced adaptations in strength is low (30% to 40%) for sedentary, untrained individuals or very high (>80%) for those already highly trained. For healthy but untrained adults, a typical training zone usually falls between 40% and 70% of the baseline RM.[8,10,14] The lower percentage of this range is safer at the beginning of a program to enable an individual to focus on learning correct exercise form and technique before progressing the exercise load to 60% to 70%.

BOX 6.5 Percentage of Body Weight as an Initial Exercise Load for Selected Exercises

- Universal bench press: 30% body weight
- Universal leg extension: 20% body weight
- Universal leg curl: 10% to 15% body weight
- Universal leg press: 50% body weight

Exercising at a low to moderate percentage of the established RM is recommended for children and the elderly.[8,10] For patients with significant deficits in muscle strength or to train for muscular endurance, using a low load—possibly at the 30% to 50% level—is safe yet challenging.

Volume

In resistance training the *volume* of exercise is the summation of the total number of repetitions and sets of a particular exercise during a single exercise session times the intensity of the exercise.[8,10,168] The same combination of repetitions and sets is not and should not be used for all muscle groups.

There is an inverse relationship between the sets and repetitions of an exercise and the intensity of the resistance. The higher the intensity (load), the lower the number of repetitions and sets possible. Conversely, the lower the load, the greater the number of repetitions and sets possible. Therefore, the exercise load directly dictates how many repetitions and sets are possible.

Repetitions. The number of repetitions in a dynamic exercise program refers to the number of times a particular movement is repeated. More specifically, it is the number of muscle contractions performed to move the limb through a series of continuous and complete excursions against a specific exercise load.

If the RM designation is used, the number of repetitions at a specific exercise load is reflected in the designation. For example, 10 repetitions at a particular exercise load is a 10-RM. If a 1-RM has been established as a baseline level of dynamic strength, a percentage of the 1-RM used as the exercise load influences the number of repetitions a patient is able to perform before fatiguing. The "average," untrained adult, when exercising with a load that is equivalent to 75% of the 1-RM, is able to complete approximately 10 repetitions before needing to rest.[18,192] At 60% intensity about 15 repetitions are possible, and at 90% intensity only 4 or 5 repetitions are usually possible.

For practical reasons, after a beginning exercise load is selected, the target number of repetitions performed for each exercise before a brief rest is often within a range rather than an exact number of repetitions. For example, a patient might be able to complete between 8 and 10 repetitions against a specified load before resting. This is sometimes referred to as a *RM zone,*[192] it gives the patient a goal but builds in some flexibility.

The number of repetitions selected depends on the patient's status and whether the goal of the exercise is to improve muscle strength or endurance. No optimal number for strength training or endurance training has been identified. Training effects (greater strength) have been reported employing a 2- to 3-RM to a 15-RM.[18,170]

Sets. A predetermined number of consecutive repetitions grouped together is known as a *set* or *bout* of exercise. After each set of a specified number of repetitions, there is a brief interval of rest. For example, during a single exercise session to strengthen a particular muscle group, a patient might be directed to lift an exercise load 8 to 10 times, rest, and then lift the load another 8 to 10 times. That would be two sets of an 8- to 10-RM.

As with repetitions, there is no optimal number of sets per exercise session, but 2 to 4 sets is a common recommendation for adults.[8] As few as one set and as many as six sets, however, have yielded positive training effects.[10,168] Single-set exercises at low intensities are most common in the very early phases of a resistance exercise program or in a maintenance program. Multiple-set exercises are used to progress the program and have been shown to be superior to single-set regimens in advanced training.[170]

Training to Improve Strength or Endurance: Impact of Exercise Load and Repetitions

Overall, because many variations of intensity and volume cause positive training-induced adaptations in muscle performance, there is a substantial amount of latitude for selecting an exercise load/repetition and set scheme for each exercise. The question becomes: Is the goal to improve strength, power, or muscular endurance?

To Improve Muscle Strength

In DeLorme's early studies,[64,65] three sets of a 10-RM performed for 10 repetitions over the training period led to gains in strength. Current recommendations for strength training vary somewhat. One resource[14] suggests that a threshold of 40% to 60% of maximum effort is necessary for adaptive strength gains to occur in a healthy but untrained individual. However, other resources recommend using a moderate exercise load (60% to 80% of a 1-RM) that causes fatigue after 8 to 12 repetitions for 2 or 3 sets.[8,168] When fatigue no longer occurs after the target number of repetitions has been completed, the level of resistance is increased to overload the muscle once again.

To Improve Muscle Endurance

Training to improve muscle (local) endurance involves performing many repetitions of an exercise against a submaximal load.[9,168,260] For example, as many as three to five sets of 40 to 50 repetitions against a low amount of weight or a light grade of elastic resistance might be used. When increasing the number of repetitions or sets becomes inefficient, the load can be increased slightly.

Endurance training also can be accomplished by maintaining an isometric muscle contraction for incrementally longer periods of time. Because endurance training is performed against very low levels of resistance, it can and should be initiated very early in a rehabilitation program without risk of injury to healing tissues.

CLINICAL TIP

When injured muscles are immobilized, type I (slow twitch) muscle fibers atrophy at a faster rate than type II (fast twitch) fibers.[206] There is also a slow to fast muscle fiber type

conversion with disuse. These changes give rise to a much faster rate of atrophy of antigravity muscles compared with their antagonists,[183] underscoring the need for early initiation of endurance training following injury or surgery.

Exercise Order

The sequence in which exercises are performed during an exercise session has an impact on muscle fatigue and adaptive training effects. When several muscle groups are exercised in a single session, as is the case in most rehabilitation or conditioning programs, large muscle groups should be exercised before small muscle groups, and multi-joint exercises should be performed before single-joint exercises.[10,103,167,168] In addition, after an appropriate warm-up, higher intensity exercises should be performed before lower intensity exercises.[10]

Frequency

Frequency in a resistance exercise program refers to the number of exercise sessions per day or per week.[8,10] Frequency also may refer to the number of times per week specific muscle groups are exercised or certain exercises are performed.[8,168] As with other aspects of dosage, frequency is dependent on other determinants, such as intensity and volume as well as the patient's goals, general health status, previous participation in a resistance exercise program, and response to training. The greater the intensity and volume of exercise, the more time is needed between exercise sessions to recover from the temporarily fatiguing effects of exercise. A common cause of a decline in performance from overtraining (see discussion later in the chapter) is excessive frequency, inadequate rest intervals, and progressive fatigue.

Some forms of exercise should be performed less frequently than others because they require greater recovery time. It has been known for some time that high-intensity *eccentric* exercise, for example, is associated with greater microtrauma to soft tissues and a higher incidence of delayed-onset muscle soreness than concentric exercise.[16,106,212] Therefore, rest intervals between exercise sessions are longer and the frequency of exercise is less than with other forms of exercise.

Although an optimal frequency per week has not been determined, a few generalizations can be made. Initially in an exercise program, short sessions of exercises sometimes can be performed on a daily basis several times per day as long as the intensity of exercise and number of repetitions are low. This frequency often is indicated for early postsurgical patients when the operated limb is immobilized and the extent of exercise is limited to nonresisted isometric (setting) exercises to minimize the risk of muscle atrophy. As the intensity and volume of exercise increases, a frequency of 2 to 3 times per week, every other day, or up to five exercise sessions per week is common.[8,10,103,167] A rest interval of 48 hours for training major muscle groups can be achieved by exercising the upper extremities one day and the lower extremities during the next exercise session.

Frequency is again reduced for a maintenance program, usually to two times per week. With prepubescent children and the very elderly, frequency typically is limited to no more than 2 to 3 sessions per week.[8,10,36,37] Highly trained athletes involved in body building, power lifting, and weight lifting, who know their own response to exercise, often train at a high-intensity and volume up to 6 days per week.[10,168,170]

Duration

Exercise *duration* is the total number of weeks or months during which a resistance exercise program is carried out. Depending on the cause of impaired muscle performance, some patients require only a month or two of training to return to the desired level of function or activity, whereas others need to continue the exercise program for a lifetime to maintain optimal function.

As noted earlier in the chapter, strength gains observed early in a resistance training program (after 2 to 3 weeks) primarily are the result of neural adaptation. For significant changes to occur in muscle, such as hypertrophy or increased vascularization, at least 6 to 12 weeks of resistance training is required.[1,8,192]

Rest Interval (Recovery Period)

Purpose of rest intervals. Rest is a critical element of a resistance training program and is necessary to allow time for the body to recuperate from the acute effects of exercise associated with muscle fatigue or to offset adverse responses, such as exercise-induced, delayed-onset muscle soreness. Only with an appropriate balance of progressive loading and adequate rest intervals can muscle performance improve. Therefore, rest between sets of exercise and between exercise sessions must be addressed.

Integration of rest into exercise. Rest intervals for each exercising muscle group are dependent on the intensity and volume of exercise. In general, the higher the intensity of exercise the longer the rest interval. For moderate-intensity resistance training, a 2- to 3-minute rest period after each set is recommended. A shorter rest interval is adequate after low-intensity exercise. Longer rest intervals (>3 minutes) are appropriate with high-intensity resistance training, particularly when exercising large, multi-joint muscles, such as the hamstrings, which tend to fatigue rapidly.[8,10] While the muscle group that was just exercised is resting, resistance exercises can be performed by another muscle group in the same extremity or by the same muscle group in the opposite extremity.

Patients with pathological conditions that make them more susceptible to fatigue, as well as children and the elderly, should rest at least 3 minutes between sets by performing a nonresisted exercise, such as low-intensity cycling, or performing the same exercise with the opposite extremity. Remember, active recovery is more efficient than passive recovery for neutralizing the effects of muscle fatigue.

Rest between exercise sessions must also be considered. When strength training is initiated at moderate intensities (typically in the intermediate phase of a rehabilitation program after soft tissue injury), a 48-hour rest interval between exercise sessions (that is, training every other day) allows the patient adequate time for recovery.

Mode of Exercise

The *mode* of exercise in a resistance exercise program refers to the form of exercise, the type of muscle contraction that occurs, and the manner in which the exercise is carried out. For example, a patient may perform an exercise dynamically or statically or in a weight-bearing or nonweight-bearing position. Mode of exercise also encompasses the form of resistance—that is, how the exercise load is applied. Resistance can be applied manually or mechanically.

As with other determinants of resistance training, the modes of exercise selected are based on a multitude of factors already highlighted throughout this section. A brief overview of the various modes of exercise is presented in this section. An in-depth explanation and analysis of each of these types of exercise can be found in the next section of this chapter and in Chapter 7.

Type of Muscle Contraction

Figure 6.4 depicts the types of muscle contraction that may be performed in a resistance exercise program and their relationships to each other and to muscle performance.[182,210,248]

- Isometric (static) or dynamic muscle contractions are two broad categories of exercise.
- Dynamic resistance exercises can be performed using *concentric* (shortening) or *eccentric* (lengthening) contractions, or both.

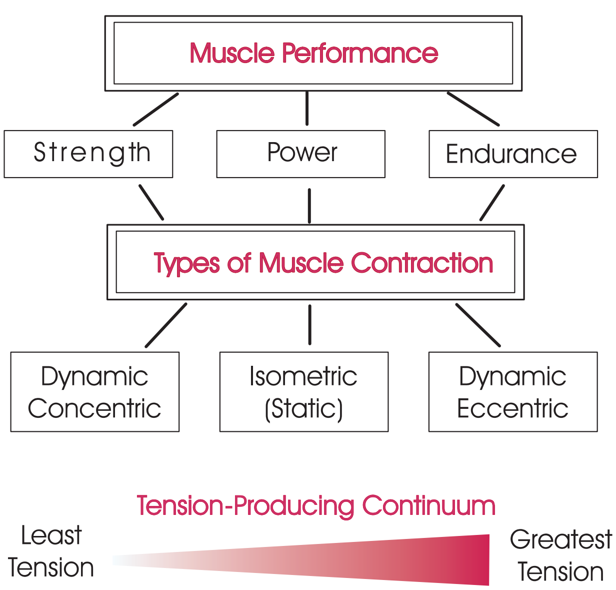

FIGURE 6.4 Types of muscle contractions: their relationships to muscle performance and their tension-generating capacities.

- When the velocity of limb movement is held consistent by a rate-controlling device, the term *isokinetic* contraction is sometimes used.[248] An alternative perspective is that this is simply a dynamic (shortening or lengthening) contraction that occurs under controlled conditions.[182]

Position for Exercise: Weight-Bearing or Nonweight-Bearing

The patient's body position or the position of a limb in nonweight-bearing or weight-bearing positions also alters the mode of exercise. When a nonweight-bearing position is assumed and the distal segment (foot or hand) moves freely during exercise, the term open-chain exercise (or a variation of this term) is often used. When a weight-bearing position is assumed and the body moves over a fixed distal segment, the term closed-chain exercise is commonly used.[182,210,248] Concepts and issues associated with the use of this terminology are addressed later in this chapter.

Forms of Resistance

- *Manual* resistance and *mechanical* resistance are the two broad methods by which resistance can be applied.
- A *constant* or *variable* load can be imposed using mechanical resistance (e.g., free weights or weight machines).
- *Accommodating* resistance[138] can be implemented by use of an isokinetic dynamometer that controls the velocity of active movement during exercise.
- *Body weight* or partial body weight is also a source of resistance if the exercise occurs in an antigravity position. Although an exercise performed against only the resistance of the weight of a body segment (and no additional external resistance) is defined as an active rather than an active-resistive exercise, a substantial amount of resistance from the weight of the body can be imposed on contracting muscles by altering a patient's position. For example, progressive loads can be placed on upper extremity musculature during push-ups by starting with wall push-ups while standing, progressing to push-ups while leaning against a countertop, push-ups in a horizontal position (Fig. 6.5), and finally push-ups from a head-down position over a large exercise ball.

FIGURE 6.5 Body weight serves as the source of resistance during a push-up.

Energy Systems

Modes of exercise also can be classified by the energy systems used during the exercise. Anaerobic exercise involves high-intensity (near-maximal) exercise carried out for a very few number of repetitions because muscles rapidly fatigue. Strengthening exercises fall into this category. Aerobic exercise is associated with low-intensity, repetitive exercise of large muscle groups performed over an extended period of time. This mode of exercise primarily increases muscular and cardiopulmonary endurance (refer to Chapter 7 for an in-depth explanation).

Range of Movement: Short-Arc or Full-Arc Exercise

Resistance through the full, available range of movement (full-arc exercise) is necessary to develop strength through the ROM. Sometimes resistance exercises are executed through only a portion of the available range. This is known as short-arc exercise. This form of exercise is used to avoid a painful arc of motion or a portion of the range in which the joint is unstable or to protect healing tissues after injury or surgery.

Mode of Exercise and Application to Function

Mode-specific training is essential if a resistance training program is to have a positive impact on function. When tissue healing allows, the type of muscle contractions performed or the position in which an exercise is carried out should mimic the desired functional activity as closely as possible.[205]

Velocity of Exercise

The velocity at which a muscle contracts significantly affects the tension that the muscle produces and subsequently affects muscular strength and power.[217] The velocity of exercise is frequently manipulated in a resistance training program to prepare the patient for a variety of functional activities that occur across a wide spectrum of slow to fast velocities.

Force-Velocity Relationship

The force-velocity relationship is different during concentric and eccentric muscle contractions, as depicted in Figure 6.6.

Concentric Muscle Contraction

During a maximum effort concentric muscle contraction, as the velocity of muscle shortening increases, the force the muscle can generate *decreases.* EMG activity and torque decrease as a muscle shortens at faster contractile velocities, possibly because the muscle may not have sufficient time to develop peak tension.[53,182,210,248,294]

Eccentric Muscle Contraction

Findings are less consistent for eccentric than concentric muscle actions. During a maximum effort eccentric contraction, as the velocity of active muscle lengthening increases, force production in the muscle initially *increases* to a point but then *quickly levels off.*[38,63,182,210,248] The initial increase in force production may be a protective response of the muscle when

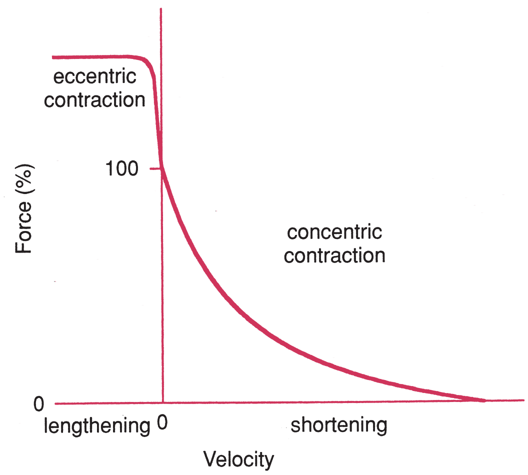

FIGURE 6.6 Force-velocity curve for concentric and eccentric exercise. *(From Levangie, PK, Norkin, CC: Joint Structure and Function—A Comprehensive Analysis, ed. 5. Philadelphia: FA Davis, 2011, p. 121, with permission.)*

it is first overloaded. It is thought that this increase may be important for shock absorption or rapid deceleration of a limb during quick changes of direction.[78,248] The rise in tension also may be caused by stretch of the noncontractile tissue in muscle.[63] In contrast, other research indicates that eccentric force production is essentially unaffected by velocity and remains constant at slow and fast velocities.[53,121]

Application to Resistance Training

A range of slow to fast exercise velocities has a place in an exercise program. Resistance training with free weights is safe and effective only at slow to medium velocities of limb movement so the patient can maintain control of the moving weight. Because many functional activities involve reasonably fast velocities of limb movement, training at only slow velocities is inadequate. The development of the isokinetic dynamometer during the late 1960s[138,200] gave clinicians a tool to implement resistance training at fast as well as slow velocities. In recent years, some variable resistance exercise units (pneumatic and hydraulic) and elastic resistance products also have afforded additional options for safely training at fast velocities.

Velocity-specific training is fundamental to a successful rehabilitation program. Results of numerous studies since the 1970s have shown that training-induced strength gains in a resistance exercise program primarily occur at the training velocities,[24,80,149] with limited transfer of training (physiological overflow) above and below the training velocities.[143,273] Accordingly, training velocities for resistance exercises should be geared to match or approach the demands of the desired functional activities.[57,149]

Isokinetic training, using *velocity spectrum rehabilitation* regimens, and *plyometric training,* also known as *stretch-shortening drills*, often emphasize high-speed training. These approaches to exercise are discussed later in this chapter and in Chapter 23, respectively.

Periodization and Variation of Training

Periodization, also known as *periodized training*, is an approach to resistance training that breaks up a training program into periods and builds *systematic variation* in exercise intensity and repetitions, sets, or frequency at regular intervals over a specified period of time.[102,168] This approach to training was developed for highly trained athletes preparing for competitive weight lifting or power lifting events. The concept was designed for optimal progression of training programs, to prevent overtraining and psychological staleness prior to competition, and to optimize performance during competition.

In preparation for competition, the training calendar is broken down into cycles, or phases, that sometimes extend over an entire year. The idea is to prepare for a "peak" performance at the time of competition. Different types of exercises at varying intensities, volume, frequency, and rest intervals are performed over a specific time period. Table 6.5 summarizes the characteristics of each cycle.

Although periodized training is commonly implemented prior to a competitive event, evidence to support the efficacy of periodization is limited.[102,170,192] Despite this, periodized training also has been used on a limited basis in the clinical setting for injured athletes during the advanced stage of rehabilitation.[96]

TABLE 6.5 Characteristics of Periodized Training

Period of Training	Intensity of Exercise	Volume and Frequency of Exercise
Preparation	Lower loads	High number of reps and sets More exercises per session More frequent exercise sessions per day and per week
Competition	Higher loads (peaking just prior to competition)	Decrease reps and sets Fewer exercises per session Less frequent exercise sessions per day per week
Recuperation	Gradual decrease in exercise loads	Additional decrease in reps, sets, number of exercises, and frequency

Integration of Function

Balance of Stability and Active Mobility

Control of the body during functional movement and the ability to perform functional tasks require a balance of active movement superimposed on a stable background of neuromuscular control. Sufficient performance of agonist and antagonist muscles about a joint contributes to the dynamic stability of individual joints. For example, a person must be able to hold the trunk erect and stabilize the spine while lifting a heavy object. Stability is also necessary to control quick changes of direction during functional movements. Hence, a resistance exercise program must address the static strength as well as the dynamic strength of the trunk and extremities.

Balance of Strength, Power, and Endurance

Functional tasks related to daily living, occupational, and recreational activities require many combinations of muscle strength, power, and endurance. Various motor tasks require slow and controlled movements, rapid movements, repeated movements, and long-term positioning. Analysis of the tasks a patient would like to be able to do provides the framework for a task-specific resistance exercise program.

Task-Specific Movement Patterns with Resistance Exercise

There is a place in a resistance exercise program for strengthening isolated muscle groups as well as strengthening muscles in combined patterns. Applying resistance during exercise in anatomical planes, diagonal patterns, and combined task-specific movement patterns should be integral components of a carefully progressed resistance exercise program. Use of simulated functional movements under controlled, supervised conditions is a means to return a patient safely to independent functional activities.[205]

Pushing, pulling, lifting, and holding activities, for example, first can be done against a low level of resistance for a limited number of repetitions. Over time, a patient can gradually return to using the same movements during functional activities in an unsupervised work or home setting. The key to successful self-management is to teach a patient how to judge the speed, level, and duration of tension generation in muscle combined with the appropriate timing that is necessary to perform a motor task safely and efficiently.

Types of Resistance Exercise

The types of exercise selected for a resistance training program are contingent on many factors, including the cause and extent of primary and secondary impairments. Deficits in muscle performance, the stage of tissue healing, the condition of joints and their tolerance to compression and movement, the general abilities (physical and cognitive) of the patient, the availability of equipment, and of course, the patient's goals and the intended functional outcomes of the program must be considered. A therapist has an array of exercises from which to choose to design a resistance exercise program to meet the individual needs of each patient. There is no one best form or type of resistance training. Prior to selecting specific types of resistance exercise for a patient's rehabilitation program, a therapist may want to consider the questions listed in Box 6.6.

BOX 6.6 Selecting Types of Resistance Exercise: Questions to Consider

- Based on the results of your examination and evaluation, what are the type and extent of the deficits in muscle performance?
- Based on the underlying pathology causing the deficits in muscle performance or the stage of tissue healing, what types of resistance exercise would be more appropriate or effective than another?
- What are the goals and anticipated functional outcomes of the resistance training program?
  - Would dynamic strength or static strength be more effective to achieve the desired outcomes?
- Which types of resistance exercise are more compatible with the desired goals?
- Are there any restrictions on how the patient is permitted or able to be positioned during exercise?
  - Is weight bearing contraindicated, restricted, or fully permissible?
  - Is there hypomobility of affected or adjacent joints (due to pain or contracture) that could affect how the patient is positioned during resistance exercise?
  - Is there a portion of the ROM in which the patient cannot safely or comfortably perform resistance exercises due to hypermobility?
  - Are there cardiovascular or respiratory impairments that could affect positioning during exercise?
- Will the patient be expected to perform the exercises independently using mechanical resistance, or would manual resistance applied by the therapist be more appropriate at this point in the rehabilitation program?
- What types of equipment will be available or needed for exercises?

Application of the SAID principle based on the concept of specificity of training is key to making sound exercise decisions. In addition to selecting the appropriate types of exercise, a therapist must also make decisions about the intensity, volume, order, frequency, rest interval, and other factors discussed in the previous section of this chapter for effective progression of resistance training. Table 6.6 summarizes general guidelines for progression of exercise.

The types of exercise presented in this section are static (isometric) and dynamic, concentric and eccentric, isokinetic, and open-chain and closed-chain exercise, as well as manual and mechanical and constant and variable resistance exercises. The benefits, limitations, and applications of each of these forms of resistance exercise are analyzed and discussed. When available, supporting evidence from the scientific literature is summarized.

Manual and Mechanical Resistance Exercise

From a broad perspective, a load can be applied to a contracting muscle in two ways: manually or mechanically. The benefits and limitations of these two forms of resistance training are summarized in a later section of this chapter (see Boxes 6.14 and 6.15).

Manual Resistance Exercise

Manual resistance exercise is a type of active-resistive exercise in which resistance is provided by a therapist or other health professional. A patient can be taught how to apply self-resistance to selected muscle groups. Although the amount of resistance cannot be measured quantitatively, this technique is useful in the early stages of an exercise program when the muscle to be strengthened is weak and can overcome only minimal

TABLE 6.6 Progression of a Resistance Training Program: Factors for Consideration

Factors	Progression
Intensity (exercise load)	Submaximal → maximal (or near-maximal) Low-load → high-load
Body position (nonweight- bearing or weight-bearing)	Variable: depending on pathology and impairments, weight-bearing restrictions (pain, swelling, instability) and goals of the rehabilitation program
Repetitions and sets	Low volume → high volume
Frequency	Variable: depends on intensity and volume of exercise
Type of muscle contraction	Static → dynamic Concentric and eccentric: variable progression
Range of motion	Short arc → full arc Stable portion of range → unstable portion of range
Plane of movement	Uniplanar → multiplanar
Velocity of movement	Slow → fast velocities
Neuromuscular control	Proximal → distal control
Functional movement patterns	Simple → complex Single joint → multijoint Proximal control → distal control

to moderate resistance. It is also useful when the range of joint movements needs to be carefully controlled. The amount of resistance given is limited only by the strength of the therapist.

NOTE: Techniques for application of manual resistance exercises in anatomical planes and diagonal patterns are presented in later sections of this chapter.

Mechanical Resistance Exercise

Mechanical resistance exercise is a form of active-resistive exercise in which resistance is applied through the use of equipment or mechanical apparatus. The amount of resistance can be measured quantitatively and incrementally progressed over time. It is also useful when the amount of resistance necessary is greater than what the therapist can apply manually.

NOTE: Systems and regimens of resistance training that involve the use of mechanical resistance, such as progressive resistive exercise (PRE), circuit weight training, and velocity spectrum rehabilitation, and the advantages and disadvantages of various types of resistance equipment are addressed later in this chapter.

Isometric Exercise (Static Exercise)

Isometric exercise is a static form of exercise in which a muscle contracts and produces force without an appreciable change in the length of the muscle and without visible joint motion.[182,210] Although there is no mechanical work done (force × distance), a measurable amount of tension and force output are produced by the muscle. Sources of resistance for isometric exercise include holding against a force applied manually, holding a weight in a particular position, maintaining a position against the resistance of body weight, or pushing or pulling an immovable object.

During the 1950s and 1960s, isometric resistance training became popular as an alternative to dynamic resistance exercise and initially was thought to be a more effective and efficient method of muscle strengthening. Isometric strength gains of 5% per week were reported when healthy subjects performed a single, near-maximal isometric contraction everyday over a 6-week period.[133] However, replications of this study called into question some of the original findings, particularly the rapid rate of strength gain.

Repetitive isometric contractions, for example a set of 20 per day, held for 6 seconds each against near-maximal resistance has since been shown to be a more effective method to improve isometric strength. A *cross-exercise effect* (a limited increase in strength of the contralateral, unexercised muscle group), as the result of transfer of training, also has been observed with maximum isometric training.[67]

Rationale for Use of Isometric Exercise

The need for static strength and endurance is apparent in almost all aspects of control of the body during functional activities. Loss of static muscle strength occurs rapidly with immobilization and disuse, with estimates from 8% per week[187] to as much as 5% per day.[208]

Functional demands often involve the need to hold a position against either a high level of resistance for a short period of time or a low level of resistance over a prolonged period of time. Of these two aspects of static muscle performance, it has been suggested that muscular endurance plays a more important role than muscle strength in maintaining sufficient postural stability and in preventing injury during daily living tasks.[192] For example, the postural muscles of the trunk and lower extremities must contract isometrically to hold the body erect against gravity and provide a background of stability for balance and functional movements in an upright position. Dynamic stability of joints is achieved by activating and maintaining a low level of co-contraction—that is, concurrent isometric contractions of antagonist muscles that surround joints.[195] The importance of isometric strength and endurance in the elbow, wrist, and finger musculature, for example, is apparent when a person holds and carries a heavy object for an extended period of time.

With these examples in mind, there can be no doubt that isometric exercises are an important part of a rehabilitation program designed to improve functional abilities. The rationale and indications for isometric exercise in rehabilitation are summarized in Box 6.7.

Types of Isometric Exercise

Several forms of isometric exercise with varying degrees of resistance and intensity of muscle contractions serve different purposes during successive phases of rehabilitation. All but one type (muscle setting) incorporate some form of significant resistance and, therefore, are used to improve static strength or develop sustained muscular control (endurance). Because no appreciable resistance is applied, muscle setting technically is not a form of resistance exercise but is included in this discussion to show a continuum of isometric exercise that can be used for multifaceted goals in a rehabilitation program.

Muscle-setting exercises. Setting exercises involve low-intensity isometric contractions performed against little to no resistance. They are used to decrease muscle pain and spasm and to promote relaxation and circulation after injury to soft tissues during the *acute* stage of healing. Two common examples of muscle setting are of the quadriceps and gluteal muscles.

Because muscle setting is performed against no appreciable resistance, it does not improve muscle strength except in very weak muscles. However, setting exercises can retard muscle atrophy and maintain mobility between muscle fibers

BOX 6.7 Isometric Exercise: Summary of Rationale and Indications

- To minimize muscle atrophy when joint movement is not possible owing to external immobilization (casts, splints, skeletal traction)
- To activate muscles (facilitate muscle firing) to begin to re-establish neuromuscular control but protect healing tissues when joint movement is not advisable after soft tissue injury or surgery
- To develop postural or joint stability
- To improve muscle strength when use of dynamic resistance exercise could compromise joint integrity or cause joint pain
- To develop static muscle strength at particular points in the ROM consistent with specific task-related needs

when immobilization of a muscle is necessary to protect healing tissues during the very early phase of rehabilitation.

Stabilization exercises. This form of isometric exercise is used to develop a submaximal but sustained level of co-contraction to improve postural stability or dynamic stability of a joint by means of midrange isometric contractions against resistance in antigravity positions and in weight-bearing postures if weight bearing is permissible.[195] Body weight or manual resistance typically is the source of resistance.

Various terms are used to describe stabilization exercises. They include *rhythmic stabilization* and *alternating isometrics*, two techniques associated with proprioceptive neuromuscular facilitation (PNF) described later in the chapter.[220,288] Stabilization exercises that focus on trunk/postural control are referred to by a variety of descriptors including *dynamic, core, and segmental* stabilization exercises. Applications of these exercises are addressed in Chapter 16. Equipment, such as the BodyBlade® (see Fig 6.50) and stability balls are designed for dynamic stabilization exercises.

Multiple-angle isometrics. This term refers to a system of isometric exercise in which resistance is applied, manually or mechanically, at multiple joint positions within the available ROM.[57] This approach is used when the goal of exercise is to improve strength throughout the ROM when joint motion is permissible but dynamic resistance exercise is painful or inadvisable.

Characteristics and Effects of Isometric Training

Effective use of isometric exercise in a resistance training program is founded on an understanding of its characteristics and its limitations.

Intensity of muscle contraction. The amount of tension that can be generated during an isometric muscle contraction depends in part on joint position and the length of the muscle at the time of contraction.[285] It is sufficient to use an exercise intensity (load) of at least 60% of a muscle's maximum voluntary contraction (MVC) to improve strength.[162,285] The amount of resistance against which the muscle is able to hold varies and needs to be adjusted at different points in the range. Resistance must be progressively increased to continue to overload the muscle as it becomes stronger.

CLINICAL TIP

When performing isometric exercises, to avoid potential injury to the contracting muscle, apply and release the resistance gradually. This helps to grade the muscle tension and ensures that the muscle contraction is pain-free. It also minimizes the risk of uncontrolled joint movement.

Duration of muscle activation. To achieve adaptive changes in static muscle performance, an isometric contraction should be held for 6 seconds and no more than 10 seconds because muscle fatigue develops rapidly. This allows sufficient time for peak tension to develop and for metabolic changes to occur in the muscle.[133,192] A 10-second contraction allows a 2-second rise time, a 6-second hold time, and a 2-second fall time.[57]

Repetitive contractions. Use of repetitive contractions, held for 6 to 10 seconds each, decreases muscle cramping and increases the effectiveness of the isometric regimen.

Joint angle and mode specificity. Gains in muscle strength occur only at or closely adjacent to the training angle.[161,162,285] Physiological overflow is minimal, occurring no more than 10° in either direction from the training angle.[162] Therefore, when performing multiple-angle isometrics, resistance at four to six points in the ROM typically is recommended. Additionally, isometric resistance training is mode-specific, causing increases in static strength with little to no impact on dynamic strength (concentric or eccentric).

Sources of resistance. It is possible to perform a variety of isometric exercises with or without equipment. For example, multiple-angle isometrics can be carried out against manual resistance or by simply having the patient push against an immovable object, such as a door frame or a wall.

Equipment designed for dynamic exercise can be adapted for isometric exercise. A weight-pulley system that provides resistance greater than the force-generating capacity of a muscle leads to a resisted isometric exercise. Most isokinetic devices can be set up with the velocity set at 0°/sec at multiple joint angles for isometric resistance at multiple points in the ROM.

PRECAUTION: Breath-holding commonly occurs during isometric exercise, particularly when performed against substantial resistance. This is likely to cause a pressor response as the result of the Valsalva maneuver, causing a rapid increase in blood pressure.[94] Rhythmic breathing, emphasizing exhalation during the contraction, should always be performed during isometric exercise to minimize this response.

CONTRAINDICATION: High-intensity isometric exercises may be contraindicated for patients with a history of cardiac or vascular disorders.

Dynamic Exercise: Concentric and Eccentric

A dynamic muscle contraction causes joint movement and excursion of a body segment as the muscle contracts and shortens (concentric muscle action) or lengthens under tension (eccentric muscle action). As represented in Figure 6.7, the term *concentric exercise* refers to a form of dynamic muscle loading in which tension in a muscle develops and physical shortening of the muscle occurs as an external force (resistance) is overcome, as when lifting a weight. In contrast, *eccentric exercise* involves dynamic loading of a muscle beyond its force-producing capacity, causing physical lengthening of the muscle as it attempts to control the load, as when lowering a weight.

During concentric and eccentric exercise, resistance can be applied in several ways: (1) constant resistance, such as body

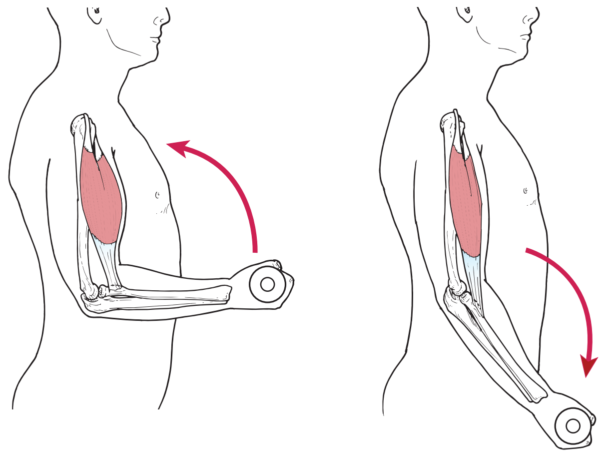

FIGURE 6.7 **(A)** Concentric and **(B)** eccentric strengthening of the elbow flexors occurs as a weight is lifted and lowered.

weight, a free weight, or a simple weight-pulley system; (2) a weight machine that provides variable resistance; or (3) an isokinetic device that controls the velocity of limb movement.

NOTE: Although the term *isotonic* (meaning equal tension) has been used frequently to describe a resisted, dynamic muscle contraction, application of this terminology is incorrect. In fact, when a body segment moves through its available range, the tension that the muscle is capable of generating *varies* through the range as the muscle shortens or lengthens. This is due to the changing length-tension relationship of the muscle and the changing torque of the load.[182,210,248] Therefore, in this textbook "isotonic" is not used to describe dynamic resistance exercise.

Rationale for Use of Concentric and Eccentric Exercise

Both concentric and eccentric exercises have distinct value in rehabilitation and conditioning programs. Concentric muscle contractions accelerate body segments, whereas eccentric contractions decelerate body segments (e.g., during sudden changes of direction or momentum). Eccentric contractions also act as a source of shock absorption during high-impact activities.[63,175]

A combination of concentric and eccentric muscle action is evident in countless tasks of daily life, such as walking up and down inclines, ascending and descending stairs, rising from a chair and sitting back down, or picking up or setting down an object. Hence, it is advisable to incorporate a variety of concentric and eccentric resistance exercises in a rehabilitation progression for patients with impaired muscle performance to improve muscle strength, power, or endurance and to meet functional demands.

Special Considerations for Eccentric Training

Eccentric training, in particular, is considered an essential component of rehabilitation programs following musculoskeletal injury or surgery and in conditioning programs to reduce the risk of injury or reinjury associated with activities that involve high-intensity deceleration, quick changes of direction, or repetitive eccentric muscle contractions.[175,213,254] Eccentric training also is thought to improve sport-related physical performance.[10,175]

Traditionally, regimens of exercise that emphasize high-intensity, eccentric loading, such as eccentric isokinetic training or *plyometric training* (see Chapter 23) have been initiated during the advanced phase of rehabilitation to prepare a patient for high-demand sports or work-related activities.[175] Recently, however, progressive eccentric training early in the rehabilitation process has been advocated to more effectively reduce deficits in strength and physical performance that often persist following a musculoskeletal injury or surgery. However, the safety of early implementation of eccentric resistance exercise must first be examined.

FOCUS ON EVIDENCE

Gerber and colleagues[111] conducted a randomized, prospective clinical trial to determine the safety and effects of a gradually progressed, eccentric exercise program initiated during the *early* phase of rehabilitation (approximately 2 to 3 weeks postoperatively) following arthroscopically assisted anterior cruciate ligament (ACL) reconstruction. All participants in the study began a 15-week traditional, but "accelerated" (early weight bearing and ROM) exercise program immediately after surgery. After the first 2 to 3 postoperative weeks, in addition to continuing the traditional program, half of the participants (experimental group) performed 12 weeks of gradually progressed, lower extremity training on a motorized eccentric ergometer. During that 12-week time period, the control group followed the same graduated program on a standard exercise cycle that provided only concentric resistance. During cycling knee ROM was limited to the 20° to 60° range of knee flexion in both groups to protect the healing ACL graft.

Knee effusion and stability and knee and thigh pain were measured preoperatively and at 15 and 26 weeks postoperatively. Quadriceps strength and one aspect of physical performance (distance of a single-leg long jump) were measured prior to surgery and again at 26 weeks after surgery. Results of the study indicated that there were no significant differences in knee or thigh pain and knee effusion and stability between groups at any point during the investigation. It is also important to note that quadriceps strength and physical performance improved significantly in the eccentric training group but not in the control group. This study demonstrated that the addition of progressively graduated eccentric resistance training during early rehabilitation following ACL reconstruction was safe and effective in reducing strength deficits and improving physical performance.

The results of a one-year follow-up study by Gerber and colleagues[112] involving 80% of the original study participants demonstrated that quadriceps strength and physical performance continued to be superior in the eccentric training group than in the group that participated in the traditional program.

Characteristics and Effects of Concentric and Eccentric Exercise

A summary of the characteristics and effects of eccentric versus concentric resistance exercise is noted in Box 6.8.

Exercise load and strength gains. A maximum concentric contraction produces less force than a maximum eccentric contraction under the same conditions (see Fig. 6.6). In other words, greater loads can be lowered than lifted. This difference in the magnitude of loads that can be controlled by concentric versus eccentric muscle contractions may be associated with the contributions of the contractile and noncontractile components of muscle. When a load is lowered during an eccentric exercise, the force exerted by the load is controlled not only by the active, contractile components of muscle but also by the noncontractile connective tissue in and around the muscle. In contrast, when a weight is lifted during concentric exercise, only the contractile components of the muscle lift the load.[63]

With a concentric contraction, greater numbers of motor units must be recruited to control the same load compared to an eccentric contraction, suggesting that concentric exercise has less mechanical efficiency than eccentric exercise.[63,78] Consequently, it requires more effort by a patient to control the same load during concentric exercise than during eccentric exercise. As a result, when a weight is lifted and lowered, maximum resistance during the concentric phase of an exercise does not provide a maximum load during the eccentric phase.

If a resistance exercise program involves maximum effort during eccentric and concentric exercise and if the exercise load is increased gradually, eccentric training increases eccentric strength over the duration of a program to a greater degree than concentric training increases concentric strength. This may occur because greater loads can be used for eccentric than concentric training.[232]

BOX 6.8 Eccentric Versus Concentric Exercise: Summary of Characteristics

- Greater loads can be controlled with eccentric than concentric exercise.
- Training-induced gains in muscle strength and mass are greater with maximum-effort eccentric training than maximum-effort concentric training.
- Adaptations associated with eccentric training are more mode- and velocity-specific than adaptations as the result of concentric training.
- Eccentric muscle contractions are more efficient metabolically and generate less fatigue than concentric contractions.
- Following *unaccustomed*, high-intensity eccentric exercise, there is greater incidence and severity delayed-onset muscle soreness than after concentric exercise.

CLINICAL TIP

Given that eccentric exercise requires recruitment of fewer motor units to control a load than concentric exercise, when a muscle is very weak—less than a fair (3/5) muscle grade—active eccentric muscle contractions against no external resistance (other than gravity) can be used to generate active muscle contractions and develop a beginning level of strength and neuromuscular control. In other words, in the presence of substantial muscle weakness, it may be easier to control lowering a limb against gravity than lifting the limb.

PRECAUTION: There is greater stress on the cardiovascular system (i.e., increased heart rate and arterial blood pressure) during eccentric exercise than during concentric exercise,[63] possibly because greater loads can be used for eccentric training. This underscores the need for rhythmic breathing during high-intensity exercise. (Refer to a later section of this chapter for additional information on cardiovascular precautions.)

Velocity of exercise. The velocity at which concentric or eccentric exercises are performed directly affects the force-generating capacity of the neuromuscular unit.[53,78] At slow velocities with a maximum load, an eccentric contraction generates greater tension than a concentric contraction. At slow velocities, therefore, a greater load (weight) can be lowered (with control) than lifted. As the velocity of exercise increases, concentric contraction tension rapidly and consistently decreases, whereas eccentric contraction forces increase slightly but then rapidly reach a plateau under maximum load conditions (see Fig. 6.6).

CLINICAL TIP

A common error made by some weightlifters during high-intensity resistance training is to assume that if a weight is lifted quickly (concentric contraction) and lowered slowly (eccentric contraction), the slow eccentric contraction generates greater tension. In fact, if the load is constant, less tension is generated during the eccentric than the concentric phase. The only way to develop greater tension is to increase the weight of the applied load during the eccentric phase of each exercise cycle. This usually requires assistance from an exercise partner to help lift the load during each concentric contraction. This is a highly intense form of exercise and should be undertaken only by healthy individuals training for high-demand sports or weight lifting competition. This technique is not appropriate for individuals recovering from musculoskeletal injuries.

Energy expenditure. Against similar exercise loads, eccentric exercise is more efficient at a metabolic level than

concentric exercise[232]—that is, eccentric muscle contractions consume less oxygen and energy stores than concentric contractions.[41] Therefore, the use of eccentric activities such as downhill running may improve muscular endurance more efficiently than similar concentric activities because muscle fatigue occurs less quickly with eccentric exercise.[63,232]

Specificity of training. Opinions and results of studies vary on whether the effects of training with concentric and eccentric contractions in the exercised muscle group are mode-specific. Although there is substantial evidence to support specificity of training,[11,24,80,205,240,275] there is also some evidence to suggest that training in one mode leads to strength gains, though less significant, in the another mode.[85] For the most part, however, eccentric training is more mode-specific than concentric training.[232] Eccentric exercise also appears to be more velocity-specific than concentric exercise.[232] Therefore, because transfer of training is quite limited, selection of exercises that simulate the functional movements needed by a patient is always a prudent choice.

Cross-training effect. Both concentric[283] and eccentric[284] training have been shown to cause a *cross-training effect*—that is, a slight increase in strength occurs over time in the same muscle group of the opposite, unexercised extremity. This effect, sometimes referred to as *cross-exercise,* also occurs with high-intensity exercise that involves a combination of concentric and eccentric contractions (lifting and lowering a weight).

This effect in the unexercised muscle group may be caused by repeated contractions of the unexercised extremity in an attempt to stabilize the body during high-effort exercise. Although cross-training is an interesting phenomenon, there is no evidence to suggest that a cross-training effect has a positive impact on a patient's functional capabilities.

Exercise-induced muscle soreness. Repeated and rapidly progressed, high-intensity eccentric muscle contractions are associated with a significantly higher incidence and severity of delayed-onset muscle soreness (DOMS) than occurs with high-intensity concentric exercise.[16,43,106,212] Why DOMS occurs more readily with eccentric exercise is speculative, possibly the result of greater damage to muscle and connective tissue when heavy loads are controlled and lowered.[16,43] It also has been suggested that the higher incidence of DOMS associated with unaccustomed, high-intensity eccentric exercise may adversely affect the training-induced gains in muscle strength.[63,80,106]

It should be noted that there is at least limited evidence to suggest that if the intensity and volume of concentric and eccentric exercise are equal, there is no significant difference in the degree of DOMS after exercise.[100] Further, if the intensity and volume of eccentric exercise is progressed gradually, DOMS does not occur.[111]

Dynamic Exercise: Constant and Variable Resistance

The most common system of resistance training used with dynamic exercise against constant or variable resistance is *progressive resistance exercise* (PRE). A later section of this chapter, which covers systems of training using mechanical resistance, addresses PRE.

Dynamic Exercise: Constant External Resistance

Dynamic exercise against constant external resistance (DCER) is a form of resistance training in which a limb moves through a ROM against a constant external load,[168] provided by free weights such as a handheld or cuff weight, torque arm units (Fig. 6.8 A), weight machines, or weight-pulley systems.

A

FIGURE 6.8 (A) N-K Exercise Unit with torque arm and interchangeable weights provides constant external resistance. *(Courtesy of N-K Products Company, Soquel, CA.);*

This terminology—DCER exercise—is used in lieu of the term "isotonic (equal tension)" exercise because although the load (weight) selected does not change, the torque imposed by the weight and the tension generated by the muscle both change throughout the range of movement.[182,248] If the imposed load is less than the torque generated by the muscle, the muscle contracts concentrically and accelerates the load; if the load exceeds the muscle's torque production, the muscle contracts eccentrically to decelerate the load (see Fig. 6.7)

DCER exercise has an inherent limitation. When lifting or lowering a constant load, the contracting muscle is challenged maximally at only one point in the ROM in which the maximum torque of the resistance matches the maximum torque output of the muscle. A therapist needs to be aware of the changing torque of the exercise and the changing length-tension relationship of the muscle and modify body position and resistance accordingly to match where in the range the

maximum load needs to be applied (see Figs. 6.46 and 6.47). Despite this limitation, DCER exercise has been and continues to be a mainstay of rehabilitation and fitness programs for effective muscle loading and subsequent training-induced improvements in muscle performance.

Variable Resistance Exercise

Variable resistance exercise, a form of dynamic exercise, addresses the primary limitation of dynamic exercise against a constant external load (DCER exercises). Specially designed resistance equipment imposes varying levels of resistance to the contracting muscles to load the muscles more effectively at multiple points in the ROM. The resistance is altered throughout the range by means of a weight-cable system that moves over an asymmetrically shaped cam, by a lever arm system (Fig. 6.8 B), or by hydraulic or pneumatic mechanisms.[249] How effectively this equipment varies the resistance to match muscle torque curves is questionable.

FIGURE 6.8—cont'd (B) Cybex/Eagle Fitness Systems shoulder press provides variable resistance throughout the range of motion. *(Courtesy of Cybex, Division of Lumex, Ronkonkoma, NY.)*

Dynamic exercise with elastic resistance products (bands and tubing) also can be thought of, in the broadest sense, as variable resistance exercise because of the inherent properties of the elastic material and its response to stretch.[146,152,243] (Refer to the final section of this chapter for additional information on exercise with elastic resistance devices.)

NOTE: When dynamic exercise is performed against manual resistance, a skilled therapist can vary the load applied to the contracting muscle throughout the ROM. The therapist adjusts the resistance based on the patient's response so the muscle is appropriately loaded at multiple portions of the ROM.

Special Considerations for DCER and Variable Resistance Exercise

Excursion of limb movement. During either DCER or variable resistance exercise, the excursion of limb movement is controlled exclusively by the patient (with the exception of exercising on resistance equipment that has a range-limiting device). When free weights, weight-pulley systems, and elastic devices are used, stabilizing muscles are recruited, in addition to the targeted muscle group, to control the arc and direction of limb movement.

Velocity of exercise. Although most daily living, occupational, and sport activities occur at medium to fast velocities of limb movement, exercises must be performed at a relatively slow-velocity to avoid momentum and uncontrolled movements, which could jeopardize the safety of the patient. (As a point of reference, dynamic exercise with a free weight typically is performed at about 60°/sec.[57]) Consequently, the training-induced improvements in muscle strength that occur only at slow velocities may not prepare the patient for activities that require rapid bursts of strength or quick changes of direction.

CLINICAL TIP

Hydraulic and pneumatic variable resistance equipment and elastic resistance products do allow safe, moderate- to high-velocity resistance training.

Isokinetic Exercise

Isokinetic exercise is a form of dynamic exercise in which the velocity of muscle shortening or lengthening and the angular limb velocity is predetermined and held constant by a rate-limiting device known as an isokinetic dynamometer (Fig. 6.9).[57,83,138,200] The term *isokinetic* refers to movement that occurs at an equal (constant) velocity. Unlike DCER exercise in which a specific weight (amount of resistance) is selected and superimposed on the contracting muscle, in isokinetic resistance training the *velocity* of limb movement—not the load—is manipulated. The force encountered by the muscle depends on the extent of force applied to the equipment.[5,138]

Isokinetic exercise is also called *accommodating resistance exercise.*[138] Theoretically, if an individual is putting forth a maximum effort during each repetition of exercise, the contracting muscle produces variable but *maximum* force output, consistent with the muscle's variable tension-generating capabilities at all portions in the range of movement, not at only one small portion of the range as occurs with DCER training. Although early advocates of isokinetic training

TABLE 6.7 Classification of Velocity of Training in Concentric Isokinetic Exercises*

Classification	Angular Velocity
Isometric	0°/sec
Slow	30°–60°/sec
Medium	60°–180°or 240°/sec
Fast	180 or°240°–360°/sec and above**

*Training velocities tend to be substantially slower for eccentric training, ranging from 30° to 120°/sec with most eccentric training initiated between 60° and 120°/sec.
**Although isokinetic equipment offers speed settings up to 500°/sec, training at velocities above 360°/sec is not frequently used because the patient must accelerate the limb to the predetermined setting before "catching" the machine—that is, before meeting resistance from the unit.

suggested it was superior to resistance training with free weights or weight-pulley systems, this claim has not been well supported by evidence. Today, use of isokinetic training is regarded as one of many tools that can be integrated into the later stages of rehabilitation.[5]

Characteristics of Isokinetic Training

A brief overview of the key characteristics of isokinetic exercise is addressed in this section. For more detailed information on isokinetic testing and training, a number of resources are available.[5,57,81,83,122]

Constant velocity. Fundamental to the concept of isokinetic exercise is that the velocity of muscle shortening or lengthening is preset and controlled by the unit and remains constant throughout the ROM.

Range and selection of training velocities. Isokinetic training affords a wide range of exercise velocities in rehabilitation from very slow to fast velocities. Current dynamometers manipulate the velocity of limb movement from 0°/sec (isometric mode) up to 500°/sec. As shown in Table 6.7, these training velocities are classified as slow, medium, and fast. This range theoretically provides a mechanism by which a patient can prepare for the demands of functional activities that occur at a range of velocities of limb movement.

Selection of training velocities should be as specific as possible to the demands of the anticipated functional tasks. The faster training velocities appear to be similar to or approaching the velocities of limb movements inherent in some functional motor skills such as walking or lifting.[5,299] For example, the average angular velocity of the lower extremity during walking has been calculated at 230° to 240°/sec.[5,57,299] Notwithstanding, the velocity of limb movements during many functional activities far exceeds the fastest training velocities available.

The training velocities selected also may be based on the mode of exercise (concentric or eccentric) to be performed. As noted in Table 6.7, the range of training velocities advocated for concentric exercise is substantially greater than for eccentric training.[5,83,122]

Reciprocal versus isolated muscle training. Use of reciprocal training of agonist and antagonist muscles emphasizing quick reversals of motion is possible on an isokinetic dynamometer. For example, the training parameter can be set so the patient performs concentric contraction of the quadriceps followed by concentric contraction of the hamstrings. An alternative approach is to target the same muscle in the concentric mode, followed by the eccentric mode, thus strengthening only one muscle group at a time.[298] Both of these approaches have merit.

Specificity of training. Isokinetic training for the most part is *velocity-specific*,[24,122,149] with only limited evidence of significant overflow from one training velocity to another.[143,273] Evidence of mode-specificity (concentric vs. eccentric) with isokinetic exercise is less clear.[12,83,121,205,240]

Because isokinetic exercise tends to be velocity-specific, patients typically exercise at several velocities (between 90° and 360°/sec) using a system of training known as *velocity spectrum rehabilitation*.[5,57,83] (This approach to isokinetic training is discussed later in this chapter.)

Compressive forces on joints. During concentric exercise, as force output decreases, the compressive forces across the moving joint are less at faster angular velocities than at slow velocities.[5,57,81,83]

Accommodation to fatigue. Because the resistance encountered is directly proportional to the force applied to the resistance arm of the isokinetic unit, as the contracting muscle fatigues, a patient is still able to perform additional repetitions even though the force output of the muscle temporarily diminishes.

Accommodation to a painful arc. If a patient experiences transient pain at some portion of the arc of motion during

exercise, isokinetic training accommodates for the painful arc. The patient simply pushes less vigorously against the resistance arm to move without pain through that portion of the range. If a patient needs to stop a resisted motion because of sudden onset of pain, the resistance is eliminated as soon as the patient stops pushing against the torque arm of the dynamometer.

Training Effects and Carryover to Function

Numerous studies have shown that isokinetic training is effective for improving one or more of the parameters of muscle performance (strength, power, and muscular endurance).[12,24,83,143,193,205] In contrast, only a limited number of studies have investigated the relationship between isokinetic training and improvement in the performance of functional skills. Two such studies indicated that the use of high-velocity concentric and eccentric isokinetic training was associated with enhanced performance (increased velocity of a tennis serve and throwing a ball).[85,201]

Limitations in carryover. Several factors inherent in the design of most types of isokinetic equipment may limit the extent to which isokinetic training carries over to improvements in functional performance. Although isokinetic training affords a spectrum of velocities for training, the velocity of limb movement during many daily living and sport-related activities far exceeds the maximum velocity settings available on isokinetic equipment. In addition, limb movements during most functional tasks occur at multiple velocities, not at a constant velocity, depending on the conditions of the task.

Furthermore, isokinetic exercise usually isolates a single muscle or opposing muscle groups, involves movement of a single joint, is uniplanar, and does not involve weight bearing. Although isolation of a single muscle can be beneficial in remediating strength deficits in specific muscle groups, most functional activities require contractions of multiple muscle groups and movement of multiple joints in several planes of motion, some in weight-bearing positions. It is important to note, however, that some of these limitations can be addressed by adapting the setup of the equipment to allow multi-axis movements in diagonal planes or multijoint resisted movements with the addition of an attachment for closed-chain training.

Special Considerations for Isokinetic Training

Availability of Equipment

From a pragmatic perspective, one limitation of isokinetic exercise is that a patient can incorporate this form of exercise into a rehabilitation program *only* by going to a facility where the equipment is available. In addition, a patient must be given assistance to set up the equipment and often requires supervision during exercise. These considerations contribute to high costs for the patient enrolled in a long-term rehabilitation program.

Appropriate Setup

The setups recommended in the product manuals often must be altered to ensure that the exercise occurs in a position that is safe for a particular joint. For example, even though a manufacturer may describe a 90°/90° position of the shoulder and elbow for strengthening the shoulder rotators, exercising with the arm at the side may be a safer, more comfortable position.

Initiation and Progression of Isokinetic Training During Rehabilitation

Isokinetic training typically is begun in the later stages of rehabilitation, when active motion through the full (or partial) ROM is pain-free. Suggested guidelines for implementation and progression are summarized in Box 6.9.[5,57,83,122]

Open-Chain and Closed-Chain Exercise

Background

In clinical practice and in the rehabilitation literature, functional activities and exercises commonly are categorized as having weight-bearing or nonweight-bearing characteristics. Another frequently used method of classifying movements and exercises is based on "open or closed kinetic chain" and "open or closed kinematic chain" concepts. These concepts, which were introduced during the 1950s and 1960s in the human biomechanics and kinesiology literature by Steindler[256] and Brunnstrom,[32] respectively, were proposed to describe how segments (structures) and motions of the body are linked and how muscle recruitment changes with different types of movement and in response to different loading conditions in the environment.

In his analysis of human motion, Steindler[256] proposed that the term "open kinetic chain" applies to completely unrestricted movement in space of a peripheral segment of the body, as in waving the hand or swinging the leg. In contrast, he suggested that during closed kinetic chain movements

BOX 6.9 Progression of Isokinetic Training for Rehabilitation

- Initially, to keep resistance low, submaximal isokinetic exercise is implemented before maximal effort isokinetic exercise.
- Short-arc movements are used before full-arc motions, when necessary, to avoid movement in an unstable or painful portion of the range.
- Slow to medium training velocities (60°–180°/sec) are incorporated into the exercise program before progressing to faster velocities.
- Maximal concentric contractions at various velocities are performed before introducing eccentric isokinetic exercises for the following reasons.
  - Concentric isokinetic exercise is easier to learn and is fully under the control of the patient.
  - During eccentric isokinetic exercise, the velocity of movement of the resistance arm is robotically controlled by the dynamometer, not the patient.

the peripheral segment meets with "considerable external resistance." He stated that if the terminal segment remains fixed, the encountered resistance moves the proximal segments over the stationary distal segments. Steindler also noted that a closed kinetic chain motion in one joint is accompanied by motions of adjacent joints that occur in reasonably predictable patterns.

Both Steindler and Brunnstrom pointed out that the action of a muscle changes when the distal segment is free to move versus when it is fixed in place. For example, in an open chain the tibialis posterior muscle functions to invert and plantarflex the foot and ankle. In contrast, during the stance phase of gait (during loading), when the foot is planted on the ground, the tibialis posterior contracts to decelerate pronation of the subtalar joint and supinate the foot to externally rotate the lower leg during mid and terminal stance.

During the late 1980s and early 1990s, clinicians and researchers in rehabilitation, who were becoming familiar with the open and closed kinetic (or kinematic) chain approach to classifying human motion, began to describe exercises based on these concepts.[221,230,274]

Controversy and Inconsistency in Use of Open-Chain and Closed-Chain Terminology

Although use of open- and closed-chain terminology to describe exercises has become prevalent in clinical practice and in the rehabilitation literature, a lack of consensus has emerged about how—or even if—this terminology should be used and what constitutes an open-chain versus a closed-chain exercise.[25,71,72,124,251,291]

One source of inconsistency is whether weight bearing is an inherent component of closed kinetic chain motions. Steindler[256] did not specify that weight bearing must occur for a motion to be categorized as closed kinetic chain, but many of his examples of closed-chain movements, particularly in the lower extremities, involved weight bearing. In the rehabilitation literature, descriptions of a closed kinetic chain often do[61,101]—but sometimes do not[127,251]—include weight bearing as a necessary element. One resource suggested that all weight-bearing exercises involve some elements of closed-chain motions, but not all closed-chain exercises are performed in weight-bearing positions.[251]

Another point of ambiguity is whether the distal segment must be absolutely fixed in place to a surface and not moving on a surface to be classified as a closed-chain motion. Steindler[256] described this as one of the conditions of a closed kinetic chain motion. However, another condition in his description of closed-chain motions is that if the "considerable external resistance" is overcome, it results in movement of the peripheral segment. Examples Steindler cited were pushing a cart away from the body and lifting a load. Consequently, some investigators have identified a bench press exercise, a seated or reclining leg press exercise, or cycling as closed-chain exercises because they involve pushing motions and axial loading.[25,60] If these exercises fit under the closed-chain umbrella, does an exercise in which the distal segment slides across the support surface also qualify as a closed-chain motion? Opinion is divided.

Lifting a handheld weight or pushing against the force arm of an isokinetic dynamometer are consistently cited in the literature as examples of open-chain exercises.* Although there is no axial loading in these exercises, considering Steindler's condition for closed-chain motion just discussed, should these exercises more correctly be classified as closed-chain rather than open-chain exercises in that the distal segment is overcoming considerable external resistance? Again, there continues to be no consensus.

Given the complexity of human movement, it is not surprising that a single classification system cannot adequately group the multitude of movements found in functional activities and therapeutic exercise interventions.

Alternatives to Open-Chain and Closed-Chain Terminology

To address the unresolved issues associated with open-chain and closed-chain terminology, several authors have offered alternative or additional terms to classify exercises. One suggestion is to use the terms, "distally fixated" and "nondistally fixated" in lieu of closed-chain and open-chain.[204] Another suggestion is to add a category dubbed partial kinetic chain[291] to describe exercises in which the distal segment (hand or foot) meets resistance but is not absolutely stationary, such as using a leg press machine, stepping machine, or slide board. The term closed kinetic chain is then reserved for instances when the terminal segment does not move.

To avoid use of the open- or closed-chain terminology, another classification system categorizes exercises as either *joint isolation exercises* (movement of only one joint segment) or *kinetic chain exercises* (simultaneous movement of multiple segments that are linked).[159,221] Boundaries of movement of the peripheral segment (movable or stationary) or loading conditions (weight-bearing or nonweight-bearing) are not parameters of this terminology. However, other, more complex classification systems do take these conditions into account.[72,181]

An additional option is to describe the specific conditions of exercises. Using this approach, most open-chain exercises could be described as single-joint weight-bearing exercises, and most closed-chain exercises would be identified as multiple-joint weight-bearing exercises.[131]

Despite the suggested alternative terminology, open- and closed-chain terminology continues to be widely used in practice settings and in the literature.† Therefore, recognizing the many inconsistencies and shortcomings of the kinetic or kinematic chain terminology and that many exercises and functional activities involve a combination of open- and closed-chain motions, the authors of this textbook have elected to continue to use open- and closed-chain terminology to describe exercises.

*60,61,86,101,127,230,257,291,296

†26,31,60,61,75,83,84,124,127,150,194,197,262,296

Characteristics of Open-Chain and Closed-Chain Exercises

The following operational definitions and characteristics of open- and closed-chain exercises are presented for clarity and as the basis for the discussion of open- and closed-chain exercises described throughout this textbook. The parameters of the definitions are those most frequently noted in the current literature. Common characteristics of open- and closed-chain exercises are compared in Table 6.8.

Open-Chain Exercises

Open-chain exercises involve motions in which the distal segment (hand or foot) is free to move in space, without necessarily causing simultaneous motions at adjacent joints.[60,84,86,101,159] Limb movement only occurs *distal* to the moving joint, and muscle activation occurs in the muscles that cross the moving joint. For example, during knee flexion in an open-chain exercise (Fig. 6.10), the action of the hamstrings is independent of recruitment of other hip or ankle musculature. Open-chain exercises also are typically performed in nonweight-bearing positions.[61,101,197,301] In addition, during resistance training, the exercise load (resistance) is applied to the moving distal segment.

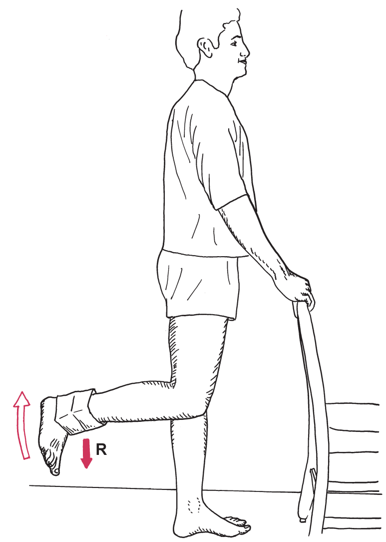

FIGURE 6.10 Open-chain resisted knee flexion.

TABLE 6.8 Characteristics of Open-Chain and Closed-Chain Exercises

Open-Chain Exercises	Closed-Chain Exercises
Distal segment moves in space.	Distal segment remains in contact with or stationary (fixed in place) on support surface.
Independent joint movement; no predictable joint motion in adjacent joints.	Interdependent joint movements; relatively predictable movement patterns in adjacent joints.
Movement of body segments only distal to the moving joint.	Movement of body segments may occur distal and/or proximal to the moving joint.
Muscle activation occurs predominantly in the prime mover and is isolated to muscles of the moving joint.	Muscle activation occurs in multiple muscle groups, both distal and proximal to the moving joint.
Typically performed in nonweight-bearing positions.	Typically but not always performed in weight-bearing positions.
Resistance is applied to the moving distal segment.	Resistance is applied simultaneously to multiple moving segments.
Use of external rotary loading.	Use of axial loading.
External stabilization (manually or with equipment) usually required.	Internal stabilization by means of muscle action, joint compression and congruency, and postural control.

Closed-Chain Exercises

Closed-chain exercises involve motions in which the body moves on a distal segment that is fixed or stabilized on a support surface. Movement at one joint causes simultaneous motions at distal as well as proximal joints in a relatively predictable manner. For example, when performing a bilateral short-arc squatting motion (mini-squat) (Fig. 6.11) and then returning to an

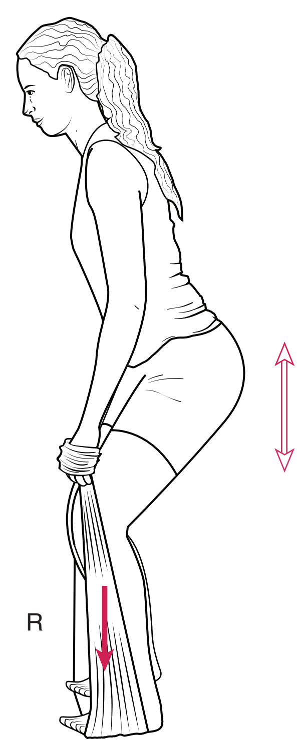

FIGURE 6.11 Bilateral closed-chain resisted hip and knee flexion/extension.

60,84,86,101,127,159,197,251,291

erect position, as the knees flex and extend, the hips and ankles move in predictable patterns.

Closed-chain exercises typically are performed in weight-bearing positions.[60,85,101,127,197,301] Examples in the upper extremities include balance activities in quadruped, press-ups from a chair, wall push-offs, or prone push-ups; examples in the lower extremities include lunges, squats, step-up or step-down exercises, or heel rises to name a few.

NOTE: In this textbook, as in some other publications,[84,86,127,262] inclusive in the scope of closed-chain exercises are *weight-bearing activities* in which the distal segment *moves but remains in contact with the support surface,* as when using a bicycle, cross-country ski machine, or stair-stepping machine. In the upper extremities a few nonweight-bearing activities qualify as closed-chain exercises, such as pull-ups on a trapeze in bed or chin-ups at an overhead bar.

Rationale for Use of Open-Chain and Closed-Chain Exercises

The rationale for selecting open- or closed-chain exercises is based on the goals of an individualized rehabilitation program and a critical analysis of the potential benefits and limitations inherent in either form of exercise. Because functional activities involve many combinations and considerable variations of open- and closed-chain motions, inclusion and integration of task-specific open-chain and closed-chain exercises into a rehabilitation or conditioning program is both appropriate and prudent.

FOCUS ON EVIDENCE

Although often suggested, there is no evidence to support the global assumption that closed-chain exercises are "more functional" than open-chain exercises. A review of the literature by Davies[58] indicated there is a substantial body of evidence that both open- and closed-chain exercises are effective for reducing deficits in muscle performance in the upper and lower extremities. However, of the studies reviewed, very few randomized, controlled trials demonstrated that these improvements in muscle performance were associated with a reduction of functional limitations or improvement in physical performance.

A summary of the benefits and limitations of open- and closed-chain exercises and the rationale for their use follows. Whenever possible, presumed benefits and limitations or comparisons of both forms of exercise are analyzed in light of existing scientific evidence. Some of the reported benefits and limitations are supported by evidence, whereas others are often founded on opinion or anecdotal reports. Evidence is presented as available.

NOTE: Most reports and investigations comparing or analyzing open- or closed-chain exercises have focused on the knee, in particular the ACL or patellofemoral joint. Far fewer articles have addressed the application or impact of open- and closed-chain exercises on the upper extremities.

Isolation of Muscle Groups

Open-chain testing and training identifies strength deficits and improves muscle performance of individual muscles or muscle groups more effectively than closed-chain exercises. The possible occurrence of substitute motions that compensate for and mask strength deficits of individual muscles is greater with closed-chain exercise than open-chain exercise.

FOCUS ON EVIDENCE

In a study of the effectiveness of a closed-chain-*only* resistance training program after ACL reconstruction, residual muscle weakness of the quadriceps femoris was identified.[250] The investigators suggested that this residual strength deficit, which altered gait, might have been avoided with the inclusion of open-chain quadriceps training in the postoperative rehabilitation program.

Control of Movements

During open-chain resisted exercises a greater level of control is possible with a *single* moving joint than with multiple moving joints as occurs during closed-chain training. With open-chain exercises, stabilization is usually applied externally by a therapist's manual contacts or with belts or straps. In contrast, during closed-chain exercises the patient most often uses muscular stabilization to control joints or structures proximal and distal to the targeted joint. The greater levels of control afforded by open-chain training are particularly advantageous during the early phases of rehabilitation.

Joint Approximation

Almost all muscle contractions have a compressive component that approximates the joint surfaces and provides stability to the joint whether in open- or closed-chain situations.[182,210,248] Joint approximation also occurs during weight bearing and is associated with lower levels of shear forces at a moving joint. This has been demonstrated at the knee (decreased anterior or posterior tibiofemoral translation)[300,301] and possibly at the glenohumeral joint.[281] The joint approximation that occurs with the axial loading and weight bearing during closed-chain exercises is thought to cause an increase in joint congruency, which in turn contributes to stability.[60,84]

Co-activation and Dynamic Stabilization

Because most closed-chain exercises are performed in weight-bearing positions, it has been assumed and commonly reported in the neurorehabilitation literature that closed-chain exercises stimulate joint and muscle mechanoreceptors, facilitate co-activation of agonists and antagonists (co-contraction), and consequently promote dynamic stability.[220,264,279] During a standing squat, for example, the quadriceps and hamstrings are thought to contract concurrently to control the knee and hip, respectively. In studies of lower extremity closed-chain

exercises and activity of the knee musculature, this assumption has been supported[30,50,292] and refuted.[87]

In the upper extremity, closed-chain exercises in weight-bearing positions are also thought to cause co-activation of the scapular and glenohumeral stabilizers and, therefore, to improve dynamic stability of the shoulder complex.[84,291] The assumption seems plausible, but evidence of co-contraction of muscles of the shoulder girdle during weight-bearing exercises, such as a prone push-up or a press-up from a chair, is limited,[176] making it difficult for clinicians to draw conclusions or make evidence-based decisions.

There is also some thought that co-activation (co-contraction) of agonist and antagonist muscle groups may occur with selected open-chain exercises. Exercise interventions—such as alternating isometrics associated with PNF,[220.264,279] some stretch-shortening drills performed in nonweight-bearing positions,[293] use of a BodyBlade® (see Fig. 6.50), and high-velocity isokinetic training—may stimulate co-activation of muscle groups to promote dynamic stability. However, evidence of this possibility is limited.

In some studies of open-chain, high-velocity, concentric isokinetic training of knee musculature,[77,123] co-activation of agonist and antagonist muscle groups was noted briefly at the end the range of knee extension. Investigators speculated that the knee flexors fired and contracted eccentrically at the end of the range of knee extension to decelerate the limb just before contact was made with the ROM stop. However in another study, there was no evidence of co-activation of knee musculature or decreased anterior tibial translation with maximum effort, slow-velocity (60°/sec), open-chain training.[173]

PRECAUTION: High-load, open-chain exercise may have an adverse effect on unstable, injured, or recently repaired joints, as demonstrated in the ACL-deficient knee.[87,150,292,300]

Proprioception, Kinesthesia, Neuromuscular Control, and Balance

Conscious awareness of joint position or movement is one of the foundations of motor learning during the early phase of training for neuromuscular control of functional movements. After soft tissue or joint injury, proprioception and kinesthesia are disrupted and alter neuromuscular control. Re-establishing the effective, efficient use of sensory information to initiate and control movement is a high priority in rehabilitation.[180] Studies of the ACL-reconstructed knee have shown that proprioception and kinesthesia do improve after rehabilitation.[19,178]

It is thought that closed-chain training provides greater proprioceptive and kinesthetic feedback than open-chain training. Theoretically, because multiple muscle groups that cross multiple joints are activated during closed-chain exercise, more sensory receptors in more muscles and intra-articular and extra-articular structures are activated to control motion than during open-chain exercises. The weight-bearing element (axial loading) of closed-chain exercises, which causes joint approximation, is believed to stimulate mechanoreceptors in muscles and in and around joints to enhance sensory input for the control of movement.*

FOCUS ON EVIDENCE

Despite the assumption that joint position or movement sense is enhanced to a greater extent under closed-chain than open-chain conditions, the evidence is mixed. The results of one study[179] indicated that in patients with unstable shoulders kinesthesia improved to a greater extent with a program of closed-chain and open-chain exercises compared to a program of only open-chain exercises. In contrast, in a comparison of the ability to detect knee position during closed-chain versus open-chain conditions, no significant difference was reported.[268]

Lastly, closed-chain positioning is the obvious choice to improve balance and postural control in the upright position. Balance training is believed to be an essential element of the comprehensive rehabilitation of patients after musculoskeletal injuries or surgery, particularly in the lower extremities, to restore functional abilities and reduce the risk of re-injury.[155] Activities and parameters to challenge the body's balance mechanisms are discussed in Chapter 8.

Carryover to Function and Injury Prevention

As already noted, there is ample evidence to demonstrate that both open- and closed-chain exercises effectively improve muscle strength, power, and endurance.[58,60,61] Evidence also suggests that if there is a comparable level of loading (amount of resistance) applied to a muscle group, EMG activity is similar regardless of whether open-chain or closed-chain exercises are performed.[25,72]

That being said, and consistent with the principles of motor learning and task-specific training, exercises should be incorporated into a rehabilitation program that simulate the desired functions if the selected exercises are to have the most positive impact on functional outcomes.[60,124,251,291]

FOCUS ON EVIDENCE

In a study of older women, stair-climbing abilities improved to a greater extent in participants who performed lower extremity strengthening exercises while standing (closed-chain exercises) and wearing a weighted backpack than those who performed traditional (open-chain) resistance exercises.[52] In another study, squatting exercises while standing, a closed-chain exercise, were shown to enhance performance of a jumping task more effectively than open-chain isokinetic knee extension exercises.[17] Closed-chain training, specifically a program of jumping activities, also has been shown to decrease landing forces through the knees and reduce the risk of knee injuries in female athletes.[134]

Implementation and Progression of Open-Chain and Closed-Chain Exercises

Principles and general guidelines for the implementation and progression of open-chain and closed-chain exercises are similar with respect to variables such as intensity, volume, frequency, and rest intervals. These variables were discussed earlier in the chapter. Relevant features of closed-chain exercises and guidelines for progression are summarized in Table 6.9.

Introduction of Open-Chain Training

Because open-chain training typically is performed in nonweight-bearing postures, it may be the only option when weight bearing is contraindicated or must be significantly restricted or when unloading in a closed-chain position is not possible. Soft tissue pain and swelling or restricted motion of any segment of the chain may also necessitate the use of open-chain exercises at adjacent joints. After a fracture of the tibia, for example, the lower extremity usually is immobilized in a long leg cast, and weight bearing is restricted for at least a few weeks. During this period, hip strengthening exercises in an open-chain manner can still be initiated and gradually progressed until partial weight bearing and closed-chain activities are permissible.

Any activity that involves open-chain motions can be easily replicated with open-chain exercises, first by developing isolated control and strength of the weak musculature and then by combining motions to simulate functional patterns.

Closed-Chain Exercises and Weight-Bearing Restrictions: Use of Unloading

If weight bearing must be restricted, a safe alternative to open-chain exercises may be to perform closed-chain exercises while partial weight bearing on the involved extremity. This is simple to achieve in the upper extremity; but in the lower extremity, because the patient is in an upright position during closed-chain exercises, axial loading in one or both lower extremities must be reduced.

Use of aquatic exercises, as described in Chapter 9, or decreasing the percentage of body weight borne on the involved lower extremity in parallel bars are both feasible unloading strategies even though each has limitations. It is difficult to control the extent of weight bearing when performing closed-chain exercises in parallel bars. In addition, lower limb movements while standing in the parallel bars or in water tend to be slower than what typically occurs during functional tasks. An alternative is the use of a harnessing system to unload the lower extremities.[157] This system enables a patient to perform a variety of closed-chain exercises and to begin ambulation on a treadmill at functional speeds early in rehabilitation.

Progression of Closed-Chain Exercises

The parameters and suggestions for progression of closed-chain activities noted in Table 6.9 are not all-inclusive and are flexible. As a rehabilitation program progresses, more advanced forms of closed-chain training, such as plyometric

TABLE 6.9 Parameters and Progression of Closed-Chain Exercises

Parameters	Progression
% Body weight	Partial → full weight-bearing (LE: aquatic exercise, parallel bars, overhead harnessing; UE: wall push-up → modified prone push-up → prone push-up) Full weight bearing + additional weight (weighted vest or belt, handheld or cuff weights, elastic resistance)
Base of support	Wide → narrow Bilateral → unilateral Fixed on support surface → sliding on support surface
Support surface	Stable → unstable/moving (LE: floor → rocker board, wobble board, sideboard, treadmill) (UE: floor, table or wall → rocker or side board, ball) Rigid → soft (floor, table → carpet, foam) Height: ground level → increasing height (Low step → high step)
Balance	With external support → no external support Eyes open → eyes closed
Exclusion of limb movement	Small → large ranges Short-arc → full-arc (if appropriate)
Plane or direction of movement	Uniplanar → multiplanar Anterior → posterior → diagonal (forward walking → retrowalking; forward step-up → backward step-up) Sagittal → frontal or transverse (forward-backward sliding → side to side sliding; forward or backward step-up → lateral step-up)
Speed of movement or directional changes	Slow → fast

training and agility drills (discussed in Chapter 23), can be introduced.[62,86] The selection and progression of activities should always be based on the discretion of the therapist and the patient's functional needs and response to exercise interventions.

General Principles of Resistance Training

The principles of resistance training presented in this section apply to the use of both manual and mechanical resistance exercises for persons of all ages, but these principles are not "set in stone." There are many instances when they may or should be modified based on the judgment of the therapist. Additional guidelines specific to the application of manual resistance exercise, PNF, and mechanical resistance exercise are addressed in later sections of this chapter.

Examination and Evaluation

As with all forms of therapeutic exercise, a comprehensive examination and evaluation is the cornerstone of an individualized resistance training program. Therefore, prior to initiating any form of resistance exercise:

- Perform a thorough examination of the patient, including a health history, systems review, and selected tests and measurements.
  - Determine qualitative and quantitative baselines of strength, muscular endurance, ROM, and overall level of functional performance against which progress can be measured.
- Interpret the findings to determine if the use of resistance exercise is appropriate or inappropriate at this time. Some questions that may need to be answered are noted in Box 6.10. Be sure to identify the most functionally relevant impairments, the goals the patient is seeking to achieve, and the expected functional outcomes of the exercise program.
- Establish how resistance training will be integrated into the plan of care with other therapeutic exercise interventions, such as stretching, joint mobilization techniques, balance training, and cardiopulmonary conditioning exercises.
- Re-evaluate periodically to document progress and determine if and how the dosage of exercises (intensity, volume, frequency, rest) and the types of resistance exercise should be adjusted to continue to challenge the patient.

BOX 6.10 Is Resistance Training Appropriate? Questions to Consider

- Were deficits in muscle performance identified? If so, do these deficits appear to be contributing to limitations of functional abilities that you have observed or the patient or family has reported?
- Could identified deficits cause future impairment of function?
- What is the irritability and current stage of healing of involved tissues?
- Is there evidence of tissue swelling?
- Is there pain? (At rest or with movement? At what portion of the ROM? In what tissues?)
- Are there other deficits (such as impaired mobility, balance, sensation, coordination, or cognition) that are adversely affecting much of the performance?
- What are the patient's goals or desired functional outcomes? Are they realistic in light of the findings of the examination?
- Given the patient's current status, are resistance exercises indicated? Contraindicated?
- Can the identified deficits in muscle performance be eliminated or minimized with resistance exercises?
- If a decision is made to prescribe resistance exercises in the treatment plan, what resistance exercises are expected to be most effective?
- Should one area of muscle performance be emphasized over another?
- Will the patient require supervision or assistance over the course of the exercise program or can the program be carried out independently?
- What is the expected frequency and duration of the resistance training program? Will a maintenance program be necessary?
- Are there any precautions specific to the patient's physical status, general health, or age that may warrant special consideration?

Preparation for Resistance Exercises

- Select and prescribe the forms of resistance exercise that are appropriate and expected to be effective, such as whether to implement manual or mechanical resistance exercises, or both.
- If implementing mechanical resistance exercise, determine what equipment is needed and available.
- Review the anticipated goals and expected functional outcomes with the patient.
- Explain the exercise plan and procedures. Be sure that the patient and/or family understands and gives consent.
- Have the patient wear nonrestrictive clothing and supportive shoes appropriate for exercise.
- If possible, select a firm but comfortable support surface for exercise.
- Demonstrate each exercise and the desired movement pattern.

Implementation of Resistance Exercises

NOTE: These general guidelines apply to the use of *dynamic* exercises against manual *or* mechanical resistance. In addition to these guidelines, refer to special considerations and guidelines

unique to the application of manual and mechanical resistance exercises in the sections of this chapter that follow.

Warm-Up

Prior to initiating resistance exercises, warm-up with light, repetitive, dynamic, site-specific movements without applying resistance. For example, prior to lower extremity resistance exercises, have the patient walk on a treadmill, if possible, for 5 to 10 minutes followed by flexibility exercises for the trunk and lower extremities.

Placement of Resistance

- Resistance typically is applied to the distal end of the segment in which the muscle to be strengthened attaches. Distal placement of resistance generates the greatest amount of external torque with the least amount of manual or mechanical resistance (load). For example, to strengthen the anterior deltoid, resistance is applied to the distal humerus as the patient flexes the shoulder (Fig. 6.12).
- Resistance may be applied across an intermediate joint if that joint is stable and pain-free and if there is adequate muscle strength supporting the joint. For example, to strengthen the anterior deltoid using mechanical resistance, a handheld weight is a common source of resistance.
- Revise the placement of resistance if pressure from the load is uncomfortable for the patient.

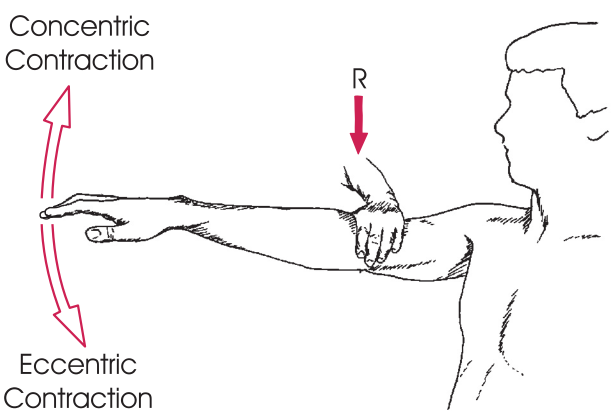

FIGURE 6.12 Resistance (R) is applied to the distal end of the segment being strengthened. Resistance is applied in the *direction opposite* to that of limb movement to resist a concentric muscle contraction and in the *same direction* as limb movement to resist an eccentric contraction.

Direction of Resistance

During concentric exercise resistance is applied in the direction directly opposite to the desired motion, whereas during eccentric exercise resistance is applied in the same direction as the desired motion (see Fig. 6.12).

Stabilization

Stabilization is necessary to avoid unwanted, substitute motions.

- For nonweight-bearing resisted exercises, external stabilization of a segment usually is applied at the proximal attachment of the muscle to be strengthened. In the case of the biceps brachii muscle, for example, stabilization should occur at the anterior shoulder as elbow flexion is resisted (Fig. 6.13). Equipment such as belts or straps are effective sources of external stabilization.
- During multijoint resisted exercises in weight-bearing postures, the patient must use muscle control (internal stabilization) to hold nonmoving segments in proper alignment.

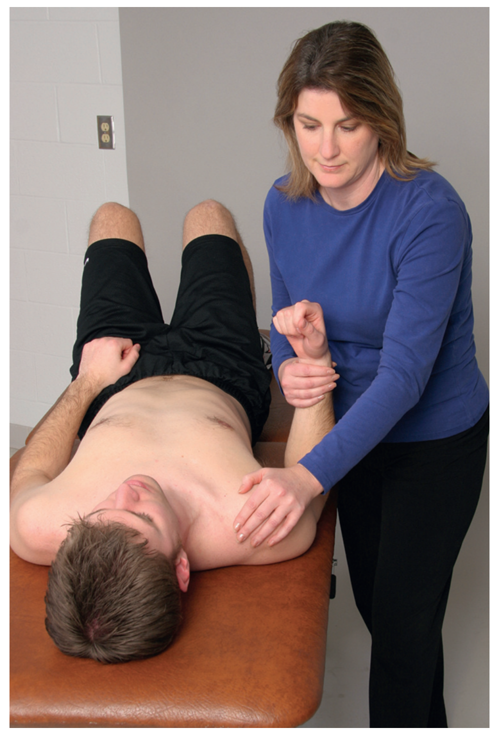

FIGURE 6.13 Stabilization is applied at the proximal attachment of the muscle being strengthened. In this figure, the proximal humerus and scapula are stabilized as elbow flexion is resisted.

Intensity of Exercise/Amount of Resistance

NOTE: The intensity of the exercise (submaximal to near-maximal) must be consistent with the intended goals of resistance training and the type of muscle contraction as well as other aspects of dosage.

- Initially, have the patient practice the movement pattern against a minimal load to learn the correct exercise technique.
- Have the patient exert a forceful but controlled and pain-free effort. The level of resistance should be such that movements are smooth and nonballistic or tremulous.

- Adjust the alignment, stabilization, or the amount of resistance if the patient is unable to complete the available ROM, muscular tremor develops, or substitute motions occur.

Number of Repetitions, Sets, and Rest Intervals

- In general, for most adults, use 8 to 12 repetitions of a specific motion against a moderate exercise load. This typically induces expected acute and chronic responses—that is, muscular fatigue and adaptive gains in muscular strength, respectively.
- Decrease the amount of resistance if the patient cannot complete 8 to 12 repetitions.
- After a brief rest, perform additional repetitions—a second set of 8 to 12 repetitions, if possible.
- For progressive overloading, initially increase the number of repetitions or sets; at a later point in the exercise program, gradually increase the resistance.

Verbal or Written Instructions

When teaching an exercise using mechanical resistance or when applying manual resistance, use simple instructions that are easily understood. Do not use medical terminology or jargon. For example, tell the patient to "Bend and straighten your elbow" rather than "Flex and extend your elbow." Be sure that descriptions of resistance exercises to be performed in a home program are written and clearly illustrated.

Monitoring the Patient

Assess the patient's responses before, during, and after exercise. It may be advisable to monitor the patient's vital signs. Adhere to relevant precautions discussed in the next section of the chapter.

Cool-Down

Cool-down after a series of resistance exercises with rhythmic, unresisted movements, such as arm swinging, walking, or stationary cycling. Gentle stretching is also appropriate after resistance exercise.

Precautions for Resistance Exercise

Regardless of the goals of a resistance exercise program and the types of exercises prescribed and implemented, the exercises must not only be effective but *safe.* The therapist's interpretation of the examination's findings determines the exercise prescription. Awareness of precautions maximizes patient safety. General precautions for resistance training are summarized in Box 6.11.

Additional information about several of these precautions is presented in this section. Special considerations and precautions for children and older adults who participate in weight-training programs are addressed later in the chapter.

BOX 6.11 General Precautions During Resistance Training

- Keep the ambient temperature of the exercise setting comfortable for vigorous exercise. Select clothing for exercise that facilitates heat dissipation and does not impede sweat evaporation.
- Caution the patient that pain should *not* occur *during* exercise.
- Do not initiate resistance training at a maximal level of resistance, particularly with eccentric exercise to minimize delayed-onset muscle soreness (DOMS). Use light to moderate exercise during the recovery period.
- Avoid use of heavy resistance during exercise for children, older adults, and patients with osteoporosis.
- Do not apply resistance across an unstable joint or distal to a fracture site that is not completely healed.
- Have the patient avoid breath-holding during resisted exercises to prevent the Valsalva maneuver; emphasize exhalation during exertion.
- Avoid uncontrolled, ballistic movements as they compromise safety and effectiveness.
- Prevent incorrect or substitute motions by adequate stabilization and an appropriate level of resistance.
- Avoid exercises that place excessive, unintended secondary stress on the back.
- Be aware of medications a patient is using that can alter acute and chronic responses to exercise.
- Avoid cumulative fatigue due to excessive frequency of exercise and the effects of overtraining or overwork by incorporating adequate rest intervals between exercise sessions to allow adequate time for recovery after exercise.
- Discontinue exercises if the patient experiences pain, dizziness, or unusual or precipitous shortness of breath.

Valsalva Maneuver

The Valsalva maneuver (phenomenon), which is defined as an expiratory effort against a closed glottis, must be avoided during resistance exercise. The Valsalva maneuver is characterized by the following sequence. A deep inspiration is followed by closure of the glottis and contraction of the abdominal muscles. This increases intra-abdominal and intrathoracic pressures, which in turn forces blood from the heart, causing an abrupt, temporary increase in arterial blood pressure.[151]

During exercise the Valsalva phenomenon occurs most often with *high-effort* isometric[94] and dynamic[186] muscle contractions. It has been shown that the rise in blood pressure induced by an isometric muscle contraction is proportional to the percentage of maximum voluntary force exerted.[186] During isokinetic (concentric) testing, if a patient exerts maximum effort at increasing velocities, the rise in blood pressure appears to be the same at all velocities of movement despite the fact that the force output of the muscle decreases.[76] Although occurrence of the Valsalva phenomenon more

often is thought to be associated with isometric[94,151] and eccentric[63] resistance exercise, a recent study[186] indicated that the rise in blood pressure appears to be based more on extent of effort—not strictly on the type (mode) of muscle contraction.

At-Risk Patients

The risk of complications from a rapid rise in blood pressure is particularly high in patients with a history of coronary artery disease, myocardial infarction, cerebrovascular disorders, or hypertension. Also at risk are patients who have undergone neurosurgery or eye surgery or who have intervertebral disk pathology. High-risk patients must be monitored closely.

CLINICAL TIP

Although resistance training is often recommended for individuals with a history of or who have a high risk for cardiovascular disorders, it is important to distinguish those individuals for whom resistance training is or is not safe and appropriate. In addition to knowledge of screening guidelines for resistance training,[7,8] close communication with a patient's physician is essential. After clearance for exercise, low-intensity resistance training (30% to 40% intensity for upper body exercises and 50% to 60% intensity for lower body exercises) typically is recommended.[7,8]

Prevention During Resistance Exercise

- Caution the patient about breath-holding.
- Ask the patient to breathe rhythmically, count, or talk during exercise.
- Have the patient exhale when lifting and inhale when lowering an exercise load.[8]
- Be certain that high-risk patients avoid high-intensity resistance exercises.

Substitute Motions

If too much resistance is applied to a contracting muscle during exercise, substitute motions can occur. When muscles are weak because of fatigue, paralysis, or pain, a patient may attempt to carry out the desired movements that the weak muscles normally perform by any means possible.[158] For example, if the deltoid or supraspinatus muscles are weak or abduction of the arm is painful, a patient elevates the scapula (shrugs the shoulder) and laterally flexes the trunk to the opposite side to elevate the arm. It may appear that the patient is abducting the arm, but in fact that is not the case. To avoid substitute motions during exercise, an appropriate amount of resistance must be applied, and correct stabilization must be used with manual contacts, equipment, or by means of muscular (internal) stabilization by the patient.

Overtraining and Overwork

Exercise programs in which heavy resistance is applied or exhaustive training is performed repeatedly must be progressed cautiously to avoid a problem known as overtraining or overwork. These terms refer to deterioration in muscle performance and physical capabilities (either temporary or permanent) that can occur in healthy individuals or in patients with certain neuromuscular disorders.

In most instances, the uncomfortable sensation associated with acute muscle fatigue induces an individual to cease exercising. This is not necessarily the case in highly motivated athletes who are said to be *overreaching* in their training program[108] or in patients who may not adequately sense fatigue because of impaired sensation associated with a neuromuscular disorder.[219]

Overtraining

The term overtraining is commonly used to describe a decline in physical performance in healthy individuals participating in high-intensity, high-volume strength and endurance training programs.[108,172] The terms chronic fatigue, staleness, and burnout are also used to describe this phenomenon. When overtraining occurs, the individual progressively fatigues more quickly and requires more time to recover from strenuous exercise because of physiological and psychological factors.

Overtraining is brought on by inadequate rest intervals between exercise sessions, too rapid progression of exercises, and inadequate diet and fluid intake. Fortunately, in healthy individuals, overtraining is a preventable, reversible phenomenon that can be resolved by tapering the training program for a period of time by periodically decreasing the volume and frequency of exercise (periodization).[108,167,170,172]

Overwork

The term *overwork*, sometimes called *overwork weakness*, refers to progressive deterioration of strength in muscles already weakened by nonprogressive neuromuscular disease.[219] This phenomenon was first observed more than 50 years ago in patients recovering from polio who were actively involved in rehabilitation.[21] In many instances the decrement in strength that was noted was permanent or prolonged. More recently, overwork weakness has been reported in patients with other nonprogressive neuromuscular diseases, such as Guillain-Barré syndrome.[56] Postpolio syndrome is also thought to be related to long-term overuse of weak muscles.[98]

Overwork weakness has been produced in laboratory animals,[129] which provides some insight as to its cause. When strenuous exercise was initiated soon after a peripheral nerve lesion, the return of functional motor strength was retarded. It was suggested that this could be caused by excessive protein breakdown in the denervated muscle.

Prevention is the key to dealing with overwork weakness. Patients in resistance exercise programs who have impaired

neuromuscular function or a systemic, metabolic, or inflammatory disease that increases susceptibility to muscle fatigue must be monitored closely, progressed slowly and cautiously, and re-evaluated frequently to determine their response to resistance training. These patients should not exercise to exhaustion and should be given longer and more frequent rest intervals during and between exercise sessions.[4,56]

Exercise-Induced Muscle Soreness

Almost every individual, unaccustomed to exercise who begins a resistance training program, particularly a program that includes eccentric exercise, experiences muscle soreness. Exercise-induced muscle soreness falls into two categories: acute and delayed onset.

Acute Muscle Soreness

Acute muscle soreness develops during or directly after strenuous exercise performed to the point of muscle exhaustion.[44] This response occurs as a muscle becomes fatigued during acute exercise because of the lack of adequate blood flow and oxygen (ischemia) and a temporary buildup of metabolites, such as lactic acid and potassium, in the exercised muscle.[9,44] The sensation is characterized as a feeling of burning or aching in the muscle. It is thought that the noxious metabolic waste products may stimulate free nerve endings and cause pain. The muscle pain experienced during intense exercise is transient and subsides quickly after exercise when adequate blood flow and oxygen are restored to the muscle. An appropriate cool-down period of low-intensity exercise (active recovery) can facilitate this process.[51]

Delayed-Onset Muscle Soreness

After vigorous and unaccustomed resistance training or any form of muscular overexertion, DOMS, which is noticeable in the muscle belly or at the myotendinous junction,[70,104,144] begins to develop approximately 12 to 24 hours after the cessation of exercise. As was already pointed out in the discussion of concentric and eccentric exercise in this chapter, high-intensity eccentric muscle contractions consistently cause the most severe DOMS symptoms.[16,63,78,100,104,215] Box 6.12 lists the signs and symptoms over the time course of DOMS. Although the time course varies, the signs and symptoms, which can last up to 10 to 14 days, gradually dissipate.[16,78,100]

BOX 6.12 Delayed-Onset Muscle Soreness: Clinical Signs and Symptoms

- Muscle soreness and aching beginning 12 to 24 hours after exercise, peaking at 48 to 72 hours, and subsiding 2 to 3 days later
- Tenderness with palpation throughout the involved muscle belly or at the myotendinous junction
- Increased soreness with passive lengthening or active contraction of the involved muscle
- Local edema and warmth
- Muscle stiffness reflected by spontaneous muscle shortening[66] before the onset of pain
- Decreased ROM during the time course of muscle soreness
- Decreased muscle strength prior to onset of muscle soreness that persists for up to 1 to 2 weeks after soreness has remitted[41]

Etiology of DOMS. Despite years of research dating back to the early 1900s,[142] the underlying mechanisms (mechanical, neural, or/or cellular) of tissue damage associated with DOMS is still unclear.[43,196] Several theories have been proposed, and some subsequently have been refuted. Early investigators proposed the *metabolic waste accumulation theory,* which suggested that both acute and delayed-onset muscle soreness was caused by a buildup of lactic acid in muscle after exercise. Although this is a source of muscle pain with acute exercise, this theory has been disproved as a cause of DOMS.[280] Multiple studies have shown that it requires only about 1 hour of recovery after exercise to exhaustion to remove almost all lactic acid from skeletal muscle and blood.[104]

The *muscle spasm theory* also was proposed as the cause of DOMS, suggesting that a feedback cycle of pain caused by ischemia and a buildup of metabolic waste products during exercise led to muscle spasm.[69] This buildup, it was hypothesized, caused the DOMS sensation and an ongoing reflex pain-spasm cycle that lasted for several days after exercise. The muscle spasm theory has been discounted in subsequent research that showed no increase in EMG activity and, therefore, no evidence of spasm in muscles with delayed soreness.[2]

Although studies on the specific etiology of DOMS continue, current research seems to suggest that DOMS is linked to some form of contraction-induced, mechanical disruption (microtrauma) of muscle fibers and/or connective tissue in and around muscle that results in degeneration of the tissue.[43,106] Evidence of tissue damage such as elevated blood serum levels of creatine kinase, is present for several days after exercise and is accompanied by inflammation and edema.[2,105,106]

The temporary loss of strength and the perception of soreness or aching associated with DOMS appear to occur independently and follow different time courses. Strength deficits develop prior to the onset of soreness and persist after soreness has remitted.[66,212] Thus, force production deficits appear to be the result of muscle damage, possibly myofibrillar damage at the Z bands,[43,211] which directly affects the structural integrity of the contractile units of muscle, not neuromuscular inhibition as the result of pain.[211,212]

Prevention and treatment of DOMS. Prevention and treatment of DOMS at the initiation of an exercise program after a short or long period of inactivity have been either ineffective or, at best, marginally successful. It is a commonly held opinion in clinical and fitness settings that the initial onset of DOMS can be prevented or at least kept to a minimum by progressing the intensity and volume of exercise

gradually,[48,78] by performing low-intensity warm-up and cool-down activities,[68,78,247] or by gently stretching the exercised muscles before and after strenuous exercise.[68,247] Although these techniques are regularly advocated and employed, little to no evidence in the literature supports their efficacy in the prevention of DOMS.

There is some evidence to suggest that the use of repetitive concentric exercise prior to DOMS-inducing eccentric exercise does not entirely prevent but does reduce the severity of muscle soreness and other markers of muscle damage.[214] Paradoxically, a regular routine of resistance exercise, particularly eccentric exercise, prior to the onset of DOMS or after an initial episode of DOMS has developed and remitted.[9,43,44,48] This response is often referred to as the "repeated-bout effect," whereby a bout of eccentric exercise protects the muscle from damage from subsequent bouts of eccentric exercise.[196] It may well be that with repeated bouts of the same level of eccentric exercise or activity that caused the initial episode of DOMS, the muscle adapts to the physical stress, resulting in the prevention of additional episodes of DOMS.[9,43,175,196]

Effective treatment of DOMS, once it has occurred, is continually being sought because, to date, the efficacy of DOMS treatment has been mixed. Evidence shows that continuation of a training program that has induced DOMS does not worsen the muscle damage or slow the recovery process.[43,215] Light, high-speed (isokinetic), concentric exercise has been reported to reduce muscle soreness and hasten the remediation of strength deficits associated with DOMS,[125] but other reports suggest no significant improvement in strength or relief of muscle soreness with light exercise.[74,282]

The value of therapeutic modalities and massage techniques also is questionable. Electrical stimulation to reduce soreness has been reported to be effective[66,153] and ineffective.[282] Although cryotherapy (cold water immersion) after vigorous eccentric exercise reduces signs of muscle damage (creatine kinase activity), it has been reported to have little to no effect on the perpetuation of muscle tenderness or strength deficit.[88] Also, there is no significant evidence that postexercise massage, despite its widespread use in sports settings, reduces the signs and symptoms of DOMS.[153,272,282] Other treatments, such as hyperbaric oxygen therapy and nutritional supplements (vitamins C and E) also have been shown to have limited benefits.[48] However, use of compression sleeves[166,171] and topical salicylate creams, which provide an analgesic effect, may also reduce the severity of and hasten the recovery from DOMS-related symptoms.

FOCUS ON EVIDENCE

In a prospective study[166,171] of DOMS that was induced by maximal eccentric exercise, the use of a compression sleeve over the exercised muscle group resulted in no increase in circumferential measurements of the upper arm (which could suggest prevention of soft tissue swelling). In participants wearing a sleeve, there was also a more rapid reduction in the perception of muscle soreness and a more rapid amelioration of deficits in peak torque than recovery from DOMS without the use of compression.

In summary, although some interventions for the treatment of DOMS appear to have potential, a definitive treatment has yet to be determined.

Pathological Fracture

When an individual with known (or at high risk for) osteoporosis or osteopenia participates in a resistance exercise program, the risk of pathological fracture must be addressed. *Osteoporosis,* which is discussed in greater detail in Chapter 11, is a systemic skeletal disease characterized by reduced mineralized bone mass that is associated with an imbalance between bone resorption and bone formation, leading to fragility of bones. In addition to the loss of bone mass, there also is narrowing of the bone shaft and widening of the medullary canal.[9,29,82,174]

The changes in bone associated with osteoporosis make the bone less able to withstand physical stress. Consequently, bones become highly susceptible to pathological fracture. A *pathological fracture* (fragility fracture) is a fracture of bone already weakened by disease that occurs as the result of minor stress to the skeletal system.[29,82,189,209] Pathological fractures most commonly occur in the vertebrae, hips, wrists, and ribs.[82,174] Therefore, to design and implement a safe exercise program, a therapist needs to know if a patient has a history of osteoporosis and, as such, an increased risk of pathological fracture. If there is no known history of osteoporosis, the therapist must be able to recognize those factors that place a patient at risk for osteoporosis.[29,54,82,174,189] As noted in Chapter 11, postmenopausal women, for example, are at high risk for primary (type I) osteoporosis. Secondary (type II) osteoporosis is associated with prolonged immobilization or disuse, restricted weight bearing, or extended use of certain medications, such as systemic corticosteroids or immunosuppressants.

Prevention of Pathological Fracture

As noted earlier in the chapter, evidence of the positive osteogenic effects of physical activity that includes resistance training has been determined. Consequently, in addition to aerobic exercises that involve weight-bearing, resistance exercises have become an essential element of rehabilitation and conditioning programs for individuals with or at risk for, osteoporosis.[8,9,226,238] Therefore, individuals who are at risk for pathological fracture often engage in resistance training.

Successful, safe resistance training must impose enough load (greater than what regularly occurs with activities of daily living) to achieve the goals of the exercise program (which include increasing bone density in addition to improving muscle performance and functional abilities) but not so heavy a load as to cause a pathological fracture. Guidelines and precautions during resistance training to reduce the risk of pathological fracture for individuals with or at risk for osteoporosis are summarized in Box 6.13.[209,226,238]

BOX 6.13 Resistance Training Guidelines and Precautions to Reduce the Risk of Pathological Fracture

- *Intensity of exercise.* Avoid high-intensity (high-load), high-volume weight training. Depending on the severity of osteoporosis, begin weight training at a (40% to 60% of 1-RM)), progressing to moderate-intensity (60% to <80% of 1-RM)).
- *Repetitions and sets.* Initially, perform only one set of several exercises 8 to 12 repetitions each for the first 6 to 8 weeks.
  - Progress intensity and volume (repetitions) gradually; eventually work up to three or four sets of each exercise at moderate levels of intensity.
- *Frequency.* Perform weight lifting exercises 2 to 3 times per week.
- *Type of exercise.* Integrate weight-bearing activities into resistance training, but use the following precautions:
  - Avoid high-impact activities such as jumping or hopping. Perform most strengthening exercises in weight-bearing postures that involve low impact, such as lunges or step-ups/step-downs against additional resistance (handheld weights, a weighted vest, or elastic resistance).
  - Avoid high-velocity movements of the spine or extremities.
  - Avoid trunk flexion with rotation and end-range resisted flexion of the spine that could place excessive loading on the anterior portion of the vertebrae, potentially resulting in anterior compression fracture, wedging of the vertebral body, and loss of height.
  - Avoid lower extremity weight-bearing activities that involve torsional movements of the hips, particularly if there is evidence of osteoporosis of the proximal femur.
  - To avoid loss of balance during lower extremity exercises while standing, have the patient hold onto a stable surface such as a countertop. If the patient is at high risk for falling or has a history of falls, perform exercises in a chair to provide weight bearing through the spine.
  - In group exercise classes, keep participant-instructor ratios low; for patients at high risk for falling or with a history of previous fracture, consider direct supervision on a one-to-one basis from another trained person.

Contraindications to Resistance Exercise

There are only a few instances when resistance exercises are contraindicated. Resistance training is most often contraindicated during periods of acute inflammation and with some acute diseases and disorders. By carefully selecting the appropriate type (mode) of exercise (static vs. dynamic; weight-bearing vs. nonweight-bearing) and keeping the initial intensity of the exercise at a low to moderate level, adverse effects from resistance training can be avoided.

Pain

If a patient experiences severe joint or muscle pain during active-free (unresisted) movements, dynamic resistance exercises should not be initiated. During testing, if a patient experiences acute muscle pain during a resisted isometric contraction, resistance exercises (static or dynamic) should not be initiated. If a patient experiences pain that cannot be eliminated by reducing the resistance, the exercise should be stopped.

Inflammation

Dynamic and static resistance training is absolutely contraindicated in the presence of inflammatory neuromuscular disease. For example, in patients with acute anterior horn cell disease (Guillain-Barré) or inflammatory muscle disease (polymyositis, dermatomyositis) resistance exercises may actually cause irreversible deterioration of strength as the result of damage to muscle. *Dynamic* resistance exercises are contraindicated in the presence of acute inflammation of a joint. The use of dynamic resisted exercise can irritate the joint and cause more inflammation. Gentle setting (static) exercises against negligible resistance are appropriate.

Severe Cardiopulmonary Disease

Severe cardiac or respiratory diseases or disorders associated with acute symptoms contraindicate resistance training. For example, patients with severe coronary artery disease, carditis, or cardiac myopathy should not participate in vigorous physical activities, including a resistance training program, nor should patients with congestive heart failure or uncontrolled hypertension or dysrhythmias.[7,8]

After myocardial infarction or coronary artery bypass graft surgery resistance training should be postponed for at least 5 weeks (that includes participation in 4 weeks of supervised cardiac rehabilitation endurance training) and clearance from the patient's physician has been received.[8]

Manual Resistance Exercise

Definition and Use

Manual resistance exercise is a form of active resistive exercise in which the resistance force is applied by the therapist to either a dynamic or a static muscular contraction.

- When joint motion is permissible, resistance usually is applied throughout the available ROM as the muscle contracts and shortens or lengthens under tension.
- Exercise is carried out in anatomical planes of motion, in diagonal patterns associated with PNF techniques,[165,279] or in combined patterns of movement that simulate functional activities.

- A specific muscle may also be strengthened by resisting the action of that muscle, as described in manual muscle-testing procedures.[137,158]
- In rehabilitation programs, manual resistance exercise, which may be preceded by active-assisted and active exercise, is part of the continuum of active exercises available to a therapist to improve or restore muscular strength and endurance.

There are many advantages to the use of manual resistance exercises, but there also are disadvantages and limitations to this form of resistance exercises. These issues are summarized in Box 6.14.

Guidelines and Special Considerations

The general principles for the application of resistance exercises discussed in the preceding section of this chapter apply to manual resistance exercise. In addition, there are some special considerations that are unique to manual resistance exercises that should be followed. The following guidelines apply to manual resistance exercise carried out in anatomical planes of motion and in diagonal patterns association with PNF.

BOX 6.14 Manual Resistance Exercise: Advantages and Disadvantages

Advantages

- Most effective during the early stages of rehabilitation when muscles are weak (4/5 or less).
- Effective form of exercise for transition from assisted to mechanically resisted movements.
- More finely graded resistance than mechanical resistance.
- Resistance is adjusted throughout the ROM as the therapist responds to the patient's efforts or a painful arc.
- Muscle works maximally at all portions of the ROM.
- The range of joint movement can be carefully controlled by the therapist to protect healing tissues or to prevent movement into an unstable portion of the range.
- Useful for dynamic or static strengthening.
- Direct manual stabilization prevents substitute motions.
- Can be performed in a variety of patient positions.
- Placement of resistance is easily adjusted.
- Gives the therapist an opportunity for direct interaction with the patient to monitor the patient's performance continually.

Disadvantages

- Exercise load (amount of resistance) is subjective; it cannot be measured or quantitatively documented for purposes of establishing a baseline and exercise-induced improvements in muscle performance.
- Amount of resistance is limited to the strength of the therapist; therefore, resistance imposed is not adequate to strengthen already strong muscle groups.
- Speed of movement is slow to moderate, which may not carry over to most functional activities.
- Cannot be performed independently by the patient to strengthen most muscle groups.
- Not useful in home program unless caregiver assistance is available.
- Labor- and time-intensive for the therapist.
- Impractical for improving muscular endurance; too time-consuming.

Body Mechanics of the Therapist

- Select a treatment table on which to position the patient that is a suitable height or adjust the height of the patient's bed, if possible, to enhance use of proper body mechanics.
- Assume a position close to the patient to avoid stresses on your low back and to maximize control of the patient's upper or lower extremity.
- Use a wide base of support to maintain a stable posture while manually applying resistance; shift your weight to move as the patient moves his or her limb.

Application of Manual Resistance and Stabilization

- Review the principles and guidelines for placement and direction of resistance and stabilization (see Figs. 6.12 and 6.13). Stabilize the proximal attachment of the contracting muscle with one hand, when necessary, while applying resistance distally to the moving segment. Use appropriate hand placements (manual contacts) to provide tactile and proprioceptive cues to help the patient better understand in which direction to move.[264]
- Grade and vary the amount of resistance to equal the abilities of the muscle through all portions of the available ROM.

CLINICAL TIP

When applying manual resistance, the therapist must possess well-developed skills in order to provide enough resistance to challenge but not overpower the patient's efforts, especially when the patient has significant weakness.

- Gradually apply and release the resistance so movements are smooth, not unexpected or uncontrolled.
- Hold the patient's extremity close to your body so some of the force applied is from the weight of your body not just the strength of your upper extremities. This enables you to apply a greater amount of resistance, particularly as the patient's strength increases.
- When applying manual resistance to alternating isometric contractions of agonist and antagonist muscles to develop joint stability, maintain manual contacts at all times as the isometric contractions are repeated. As a transition is made from one muscle contraction to another, no abrupt relaxation phase or joint movements should occur between the opposing contractions.

Verbal Commands

- Coordinate the timing of the verbal commands with the application of resistance to maintain control when the patient initiates a movement.

- Use simple, direct verbal commands.
- Use different verbal commands to facilitate isometric, concentric, or eccentric contractions. To resist an *isometric* contraction, tell the patient to "Hold" or "Don't let me move you" or "Match my resistance." To resist a *concentric* contraction, tell the patient to "Push" or "Pull." To resist an *eccentric* contraction, tell the patient to "Slowly let go as I push or pull you."

Number of Repetitions and Sets/Rest Intervals

- As with all forms of resistance exercise, the number of repetitions is dependent on the response of the patient.
- For manual resistance exercise, the number of repetitions also is contingent on the strength and endurance of the therapist.
- Build in adequate rest intervals for the patient *and* the therapist; after 8 to 12 repetitions, both the patient and the therapist typically begin to experience some degree of muscular fatigue.

Techniques: General Background

The manual resistance exercise techniques described in this section are for the upper and lower extremities, performed concentrically in anatomical planes of motion. The direction of limb movement would be the opposite if manual resistance were applied to an eccentric contraction. The exercises described are performed in nonweight-bearing positions and involve movements to isolate individual muscles or muscle groups.

Consistent with Chapter 3, most of the exercises described and illustrated in this section are performed with the patient in a *supine position*. Variations in the therapist's position and hand placements may be necessary, depending on the size and strength of the therapist and the patient. Alternative patient positions, such as prone or sitting, are described when appropriate or necessary. Ultimately, a therapist must be versatile and able to apply manual resistance with the patient in all positions to meet the needs of many patients with significant differences in abilities, limitations, and pathologies.

NOTE: In all illustrations in this section, the direction in which resistance (R) is applied is indicated with a solid arrow.

Reciprocal motions, such as flexion/extension and abduction/adduction, are often alternately resisted in an exercise program in which strength and balanced neuromuscular control in both agonists and antagonists are desired. Resistance to reciprocal movement patterns also enhances a patient's ability to reverse the direction of movement smoothly and quickly, a neuromuscular skill that is necessary in many functional activities. Reversal of direction requires muscular control of both prime movers and stabilizers and combines concentric and eccentric contractions to decrease momentum and make a controlled transition from one direction to the opposite direction of movement.

Manual resistance in diagonal patterns associated with PNF are described and illustrated in the next section of this chapter. Additional resistance exercises to increase strength, power, endurance, and neuromuscular control in the extremities can be found in Chapters 17 through 23. In these chapters many examples and illustrations of resisted eccentric exercises, exercises in weight-bearing (closed-chain) positions, and exercises in functional movement patterns are featured. Resistance exercises for the cervical, thoracic, and lumbar spine are described and illustrated in Chapter 16.

Upper Extremity

Shoulder Flexion VIDEO 6.1

Hand Placement and Procedure

- Apply resistance to the anterior aspect of the distal arm or to the distal portion of the forearm if the elbow is stable and pain-free (Fig. 6.14).
- Stabilization of the scapula and trunk is provided by the treatment table.

FIGURE 6.14 Resisted shoulder flexion.

Shoulder Extension

Hand Placement and Procedure

- Apply resistance to the posterior aspect of the distal arm or the distal portion of the forearm.
- Stabilization of the scapula is provided by the table.

Shoulder Hyperextension

The patient assumes the supine position, close to the edge of the table, side-lying, or prone so hyperextension can occur.

Hand Placement and Procedure

- Apply resistance in the same manner as for extension of the shoulder.
- Stabilize the anterior aspect of the shoulder if the patient is supine.
- If the patient is side-lying, adequate stabilization must be given to the trunk and scapula. This usually can be done if the therapist places the patient close to the edge of the table and stabilizes the patient with the lower trunk.
- If the patient is lying prone, manually stabilize the scapula.

Shoulder Abduction and Adduction

Hand Placement and Procedure

- Apply resistance to the distal portion of the arm with the patient's elbow flexed to 90°. To resist abduction (Fig. 6.15), apply resistance to the lateral aspect of the arm. To resist adduction, apply resistance to the medial aspect of the arm.
- Stabilization (although not pictured in Fig. 6.15) is applied to the superior aspect of the shoulder, if necessary, to prevent the patient from *initiating* abduction by shrugging the shoulder (elevation of the scapula).

PRECAUTION: Allow the glenohumeral joint to externally rotate when resisting abduction above 90° to prevent impingement.

FIGURE 6.15 Resisted shoulder abduction.

Elevation of the Arm in the Plane of the Scapula ("Scaption")

Hand Placement and Procedure

- Same as previously described for shoulder flexion.
- Apply resistance as the patient elevates the arm in the plane of the scapula (30° to 40° anterior to the frontal plane of the body).[55,73,182]

CLINICAL TIP

Although "scaption" is not a motion of the shoulder that occurs in one of the anatomical planes of the body, resistance in the scapular plane is thought to have its merits. The evidence is inconclusive[55,237,289] as to whether the torque-producing capabilities of the key muscle groups of the glenohumeral joint are greater when the arm elevates in the plane of the scapula versus the frontal or sagittal planes. However, the glenohumeral joint has been shown to be more stable, and there is less risk of impingement of soft tissues when strength training is performed in the scapular plane.[73] (See additional discussion in Chapter 17.)

Shoulder Internal and External Rotation

Hand Placement and Procedure

- Flex the elbow to 90° and position the shoulder in the plane of the scapula.
- Apply resistance to the distal portion of the forearm during internal rotation and external rotation (Fig. 6.16A).
- Stabilize at the level of the clavicle during internal rotation; the back and scapula are stabilized by the table during external rotation.

Alternate Procedure

Alternate alignment of the humerus (Fig. 6.16 B). If the mobility and stability of the glenohumeral joint permit, the shoulder can be positioned in 90° of abduction during resisted rotation.

FIGURE 6.16 (A) Resisted external rotation of the shoulder with the shoulder positioned in flexion and abduction (approaching the plane of the scapula).

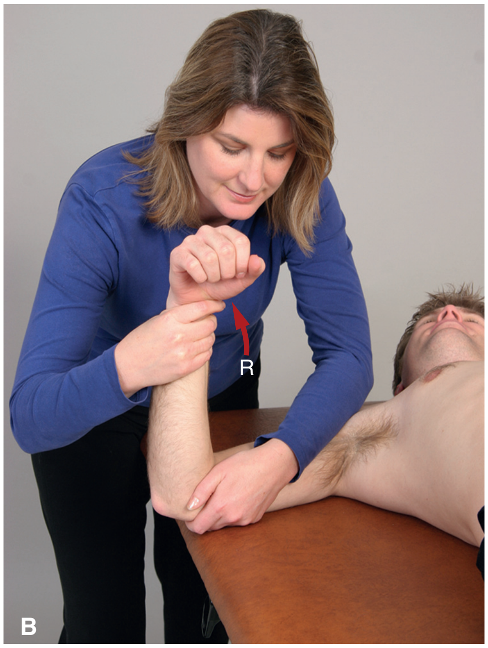

FIGURE 6.16—cont'd **(B)** Resisted internal rotation of the shoulder with the shoulder in 90° of abduction.

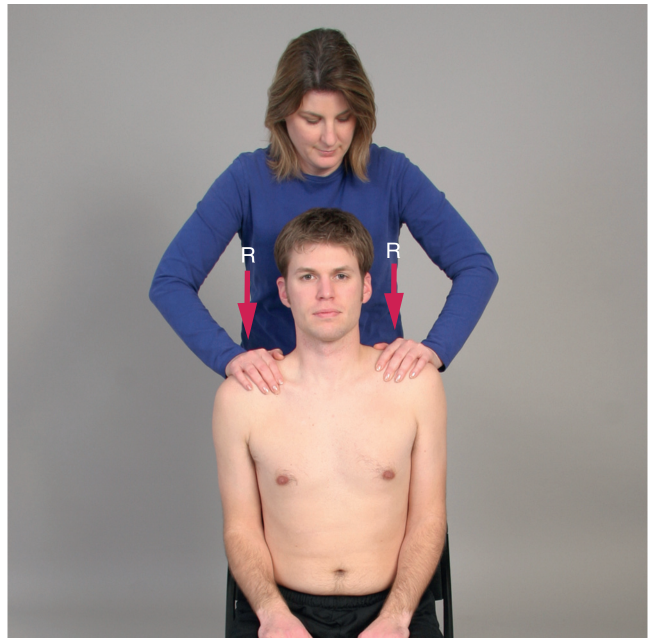

FIGURE 6.17 Elevation of the shoulders (scapulae), resisted bilaterally.

Shoulder Horizontal Abduction and Adduction

Hand Placement and Procedure

- Flex the shoulder and elbow to 90° and place the shoulder in neutral rotation.
- Apply resistance to the distal portion of the arm just above the elbow during horizontal adduction and abduction.
- Stabilize the anterior aspect of the shoulder during horizontal adduction. The table stabilizes the scapula and trunk during horizontal abduction.
- To resist horizontal abduction from 0° to 45°, the patient must be close to the edge of the table while supine or be placed side-lying or prone.

Elevation and Depression of the Scapula

VIDEO 6.2

Hand Placement and Procedure

- Have the patient assume a supine, side-lying, or sitting position.
- Apply resistance along the superior aspect of the shoulder girdle just above the clavicle during scapular elevation (Fig. 6.17).

Alternate Procedures: Scapular Depression

To resist unilateral scapular depression in the supine position, have the patient attempt to reach down toward the foot and push the hand into the therapist's hand. When the patient has adequate strength, the exercise can be performed to include weight bearing through the upper extremity by having the patient sit on the edge of a low table and lift the body weight with both hands.

Protraction and Retraction of the Scapula

Hand Placement and Procedure

- Apply resistance to the anterior portion of the shoulder at the head of the humerus to resist protraction and to the posterior aspect of the shoulder to resist retraction.
- Resistance may also be applied directly to the scapula if the patient sits or lies on the side, facing the therapist.
- Stabilize the trunk to prevent trunk rotation.

Elbow Flexion and Extension VIDEO 6.3

Hand Placement and Procedure

- To strengthen the elbow flexors, apply resistance to the anterior aspect of the distal forearm (Fig. 6.18).
- The forearm may be positioned in supination, pronation, and neutral to resist individual flexor muscles of the elbow.
- To strengthen the elbow extensors, place the patient prone (Fig. 6.19) or supine and apply resistance to the distal aspect of the forearm.
- Stabilize the upper portion of the humerus during both motions.

FIGURE 6.18 Resisted elbow flexion with proximal stabilization.

FIGURE 6.20 Resisted pronation of the forearm.

FIGURE 6.19 Resisted elbow extension.

Forearm Pronation and Supination VIDEO 6.4

Hand Placement and Procedure

- Apply resistance to the radius of the distal forearm with the patient's elbow flexed to 90° (Fig. 6.20) to prevent rotation of the humerus.

PRECAUTION: Do not apply resistance to the hand to avoid twisting forces at the wrist.

Wrist Flexion and Extension VIDEO 6.5

Hand Placement and Procedure

- Apply resistance to the volar and dorsal aspects of the hand at the level of the metacarpals to resist flexion and extension, respectively (Fig. 6.21).
- Stabilize the volar or dorsal aspect of the distal forearm.

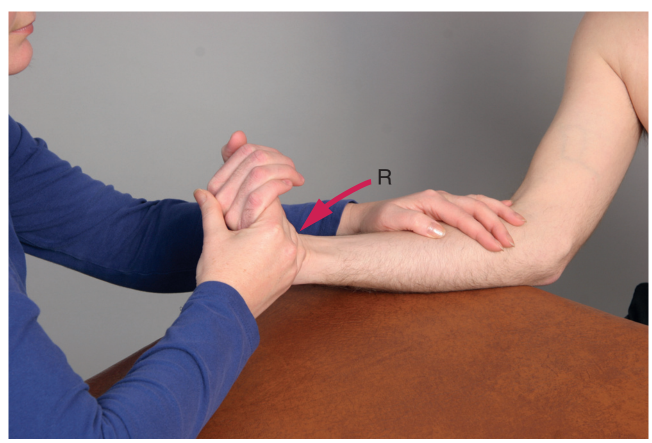

FIGURE 6.21 Resisted wrist flexion and stabilization of the forearm.

Wrist Radial and Ulnar Deviation

Hand Placement and Procedure

- Apply resistance to the second and fifth metacarpals alternately to resist radial and ulnar deviation.
- Stabilize the distal forearm.

Motions of the Fingers and Thumb VIDEO 6.6

Hand Placement and Procedure

- Apply resistance just distal to the joint that is moving. Resistance is applied to one joint motion at a time (Figs. 6.22 and 6.23).
- Stabilize the joints proximal and distal to the moving joint.

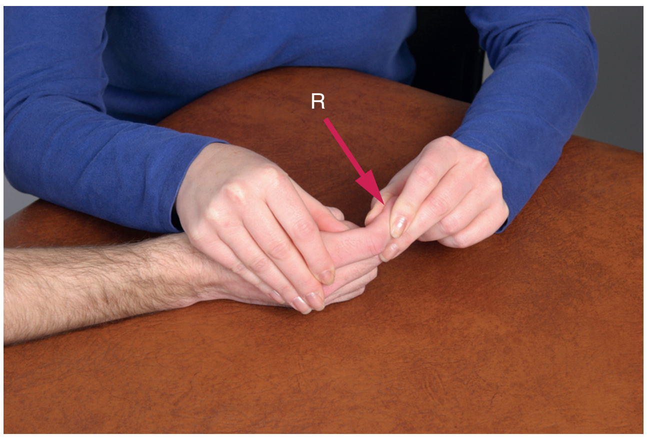

FIGURE 6.22 Resisted flexion of the proximal interphalangeal (PIP) joint of the index finger with stabilization of the metacarpophalangeal (MCP) and distal interphalangeal (DIP) joints.

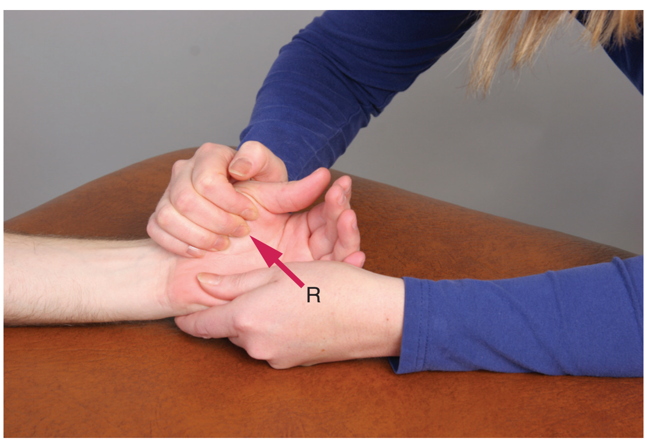

FIGURE 6.23 Resisted opposition of the thumb.

Lower Extremity

Hip Flexion with Knee Flexion VIDEO 6.7

Hand Placement and Procedure

- Apply resistance to the anterior portion of the distal thigh (Fig. 6.24). Simultaneous resistance to knee flexion may be applied at the distal and posterior aspect of the lower leg, just above the ankle.
- Stabilization of the pelvis and lumbar spine is provided by adequate strength of the abdominal muscles.

PRECAUTION: If, when the opposite hip is extended, the pelvis rotates anteriorly, and lordosis in the lumbar spine increases during resisted hip flexion, have the patient flex the opposite hip and knee and plant the foot on the table to stabilize the pelvis and protect the low back region.

FIGURE 6.24 Resisted flexion of the hip with the knee flexed.

Hip Extension

Hand Placement and Procedure

- Apply resistance to the posterior aspect of the distal thigh with one hand and to the inferior and distal aspect of the heel with the other hand (Fig. 6.25).
- Stabilization of the pelvis and lumbar spine is provided by the table.

FIGURE 6.25 Resisted hip and knee extension with the hand placed at the popliteal space to prevent hyperextension of the knee.

Hip Hyperextension

Patient position: prone.

Hand Placement and Procedure

- With the patient in a prone position, apply resistance to the posterior aspect of the distal thigh (Fig. 6.26).
- Stabilize the posterior aspect of the pelvis to avoid motion of the lumbar spine.

FIGURE 6.26 Resisted end-range hip extension with stabilization of the pelvis.

Hip Abduction and Adduction

Hand Placement and Procedure

- Apply resistance to the lateral and the medial aspects of the distal thigh to resist abduction (Fig. 6.27) and adduction, respectively, or to the lateral and medial aspects of the distal leg just above the malleoli if the knee is stable and pain-free.
- Stabilization is applied to the pelvis to avoid hip-hiking from substitute action of the quadratus lumborum and to keep the thigh in neutral position to prevent external rotation of the femur and subsequent substitution by the iliopsoas.

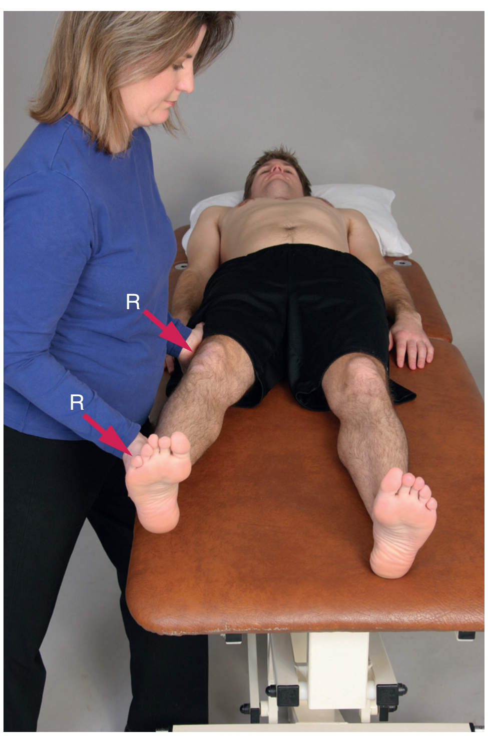

FIGURE 6.27 Resisted hip abduction.

Hip Internal and External Rotation

Patient position: supine with the hip and knee extended.

Hand Placement and Procedure

- Apply resistance to the lateral aspect of the distal thigh to resist external rotation and to the medial aspect of the thigh to resist internal rotation.
- Stabilize the pelvis.

Patient position: supine with the hip and knee flexed (Fig. 6.28).

FIGURE 6.28 Resisted external rotation of the hip with the patient lying supine.

Hand Placement and Procedure

- Apply resistance to the medial aspect of the lower leg just above the malleolus during external rotation and to the lateral aspect of the lower leg during internal rotation.
- Stabilize the anterior aspect of the pelvis as the thigh is supported to keep the hip in 90° of flexion.

Patient position: prone, with the hip extended and the knee flexed (Fig. 6.29).

Hand Placement and Procedure

- Apply resistance to the medial and lateral aspects of the lower leg.
- Stabilize the pelvis by applying pressure across the buttocks.

FIGURE 6.29 Resisted internal rotation of the hip with the patient lying prone.

Knee Flexion VIDEO 6.8

- Resistance to knee flexion may be combined with resistance to hip flexion, as described earlier with the patient supine.

Alternate patient position: prone with the hips extended (Fig. 6.30).

Hand Placement and Procedure

- Apply resistance to the posterior aspect of the lower leg just above the heel.
- Stabilize the posterior pelvis across the buttocks.

Additional patient position: sitting at the edge of a table with the hips and knees flexed and the back supported and stabilized.

FIGURE 6.30 Resisted knee flexion with stabilization of the hip.

Knee Extension

Alternate Patient Positions

- If the patient is lying supine on a table, the hip must be abducted and the knee flexed so the lower leg is over the side of the table. This position should not be used if the rectus femoris or iliopsoas is tight because it causes an anterior tilt of the pelvis and places stress on the low back.
- If the patient is prone, place a rolled towel under the anterior aspect of the distal thigh; this allows the patella to glide normally during knee extension.
- If the patient is sitting, place a rolled towel under the posterior aspect of the distal thigh (Fig. 6.31).

Hand Placement and Procedure

- Apply resistance to the anterior aspect of the lower leg.
- Stabilize the femur, pelvis, or trunk as necessary.

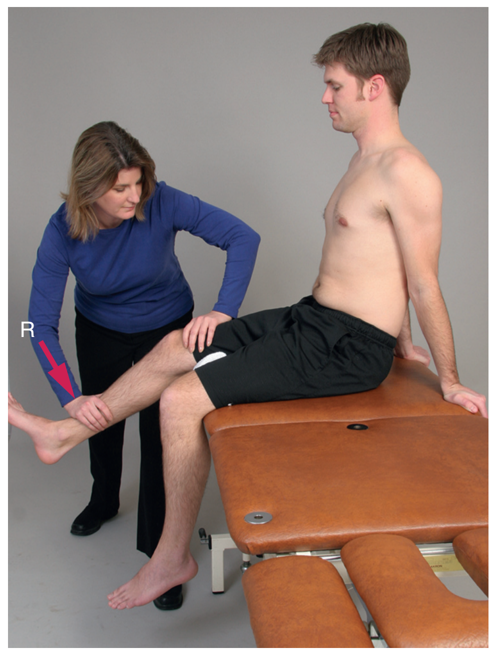

FIGURE 6.31 Resisted knee extension with the patient sitting and stabilizing the trunk with the upper extremities and the therapist stabilizing the thigh.

Ankle Dorsiflexion and Plantarflexion VIDEO 6.9

Hand Placement and Procedure

- Apply resistance to the dorsum of the foot just above the toes to resist dorsiflexion (Fig. 6.32 A) and to the plantar surface of the foot at the metatarsals to resist plantarflexion (Fig. 6.32 B).
- Stabilize the lower leg.

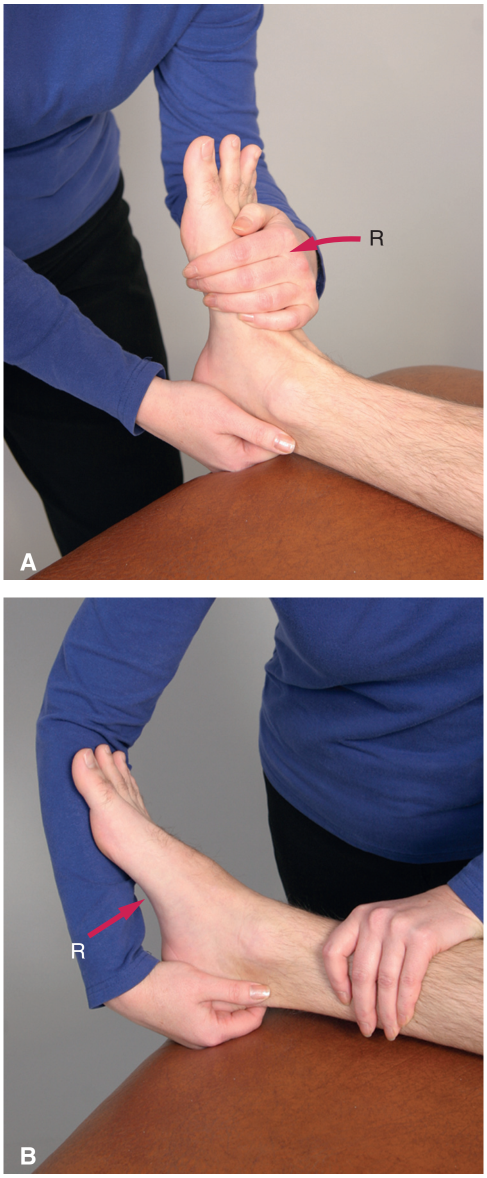

FIGURE 6.32 (A) Resisted dorsiflexion. (B) Resisted plantarflexion of the ankle.

Ankle Inversion and Eversion

Hand Placement and Procedure

- Apply resistance to the medial aspect of the first metatarsal to resist inversion and to the lateral aspect of the fifth metatarsal to resist eversion.
- Stabilize the lower leg.

Flexion and Extension of the Toes

Hand Placement and Procedure

- Apply resistance to the plantar and dorsal surfaces of the toes as the patient flexes and extends the toes.
- Stabilize the joints above and below the joint that is moving.

Proprioceptive Neuromuscular Facilitation: Principles and Techniques

PNF is an approach to therapeutic exercise that combines functionally based diagonal patterns of movement with techniques of neuromuscular facilitation to evoke motor responses and improve neuromuscular control and function. This widely used approach to exercise was developed during the 1940s and 1950s by the pioneering work of Kabat, Knott, and Voss.[165] Their work integrated the analysis of movement during functional activities with then current theories of motor development, control, and learning and principles of neurophysiology as the foundations of their approach to exercise and rehabilitation. Long associated with neurorehabilitation, PNF techniques also have widespread application for rehabilitation of patients with musculoskeletal conditions that result in altered neuromuscular control of the extremities, neck, and trunk.[132,264,277]

PNF techniques can be used to develop muscular strength and endurance; to facilitate stability, mobility, neuromuscular control, and coordinated movements; and to lay a foundation for the restoration of function. PNF techniques are useful throughout the continuum of rehabilitation from the early phase of tissue healing when isometric techniques are appropriate to the final phase of rehabilitation when high-velocity, diagonal movements can be performed against maximum resistance.

Hallmarks of this approach to therapeutic exercise are the use of diagonal patterns and the application of sensory cues—specifically proprioceptive, cutaneous, visual, and auditory stimuli—to elicit or augment motor responses. Embedded in this philosophy and approach to exercise is that the stronger muscle groups of a diagonal pattern facilitate the responsiveness of the weaker muscle groups. The focus of discussion of PNF in this chapter deals with the use of PNF patterns and techniques as an important form of resistance exercise for the development of strength, muscular endurance, and dynamic stability.

Although PNF patterns for the extremities can be performed unilaterally or bilaterally and in a variety of weight-bearing and nonweight-bearing positions, only unilateral patterns with the patient in a supine position are described and illustrated. In Chapter 4 of this text, the use of PNF stretching techniques—specifically contract-relax and hold-relax techniques and other variations—to increase flexibility are described. As noted in Chapter 3, diagonal patterns also can be used for passive and active ROM. Additional application of diagonal patterns for the extremities and trunk, some using resistance equipment, are described in the regional chapters later in this text.

Diagonal Patterns

The patterns of movement associated with PNF are composed of *multijoint*, *multiplanar*, *diagonal*, and *rotational* movements of the extremities, trunk, and neck. Multiple muscle groups contract simultaneously. There are two pairs of diagonal patterns for the upper and lower extremities: diagonal 1 (D_1) and diagonal 2 (D_2). Each of these patterns can be performed in either flexion or extension. Hence, the terminology used is D_1Flexion or D_1Extension and D_2Flexion or D_2Extension of the upper or lower extremities. The patterns are identified by the motions that occur at proximal pivot points—the shoulder or the hip joints. In other words, a pattern is named by *the position of the shoulder or hip when the diagonal pattern has been completed.* Flexion or extension of the shoulder or hip is coupled with abduction or adduction as well as external or internal rotation. Motions of body segments distal to the shoulder or hip also occur simultaneously during each diagonal pattern. Table 6.10 summarizes the component motions of each of the diagonal patterns.

As mentioned, the diagonal patterns can be carried out unilaterally or bilaterally. Bilateral patterns can be done *symmetrically* (e.g., D_1Flexion of both extremities); *asymmetrically* (D_1Flexion of one extremity coupled with D_2Flexion of the other extremity); or *reciprocally* (D_1Flexion of one extremity and D_1 Extension of the opposite extremity). Furthermore, there are patterns specifically for the scapula or pelvis and techniques that integrate diagonal movements into functional activities, such as rolling, crawling, and walking. There are several in-depth resources that describe and illustrate the many variations and applications of PNF techniques.[220,264,279]

Basic Procedures with PNF Patterns

A number of basic procedures that involve the application of multiple types of sensory cues are superimposed on the diagonal patterns to elicit the best possible neuromuscular responses.[220,264,279] Although the diagonal patterns can be used with various forms of mechanical resistance (e.g., free weights, simple weight-pulley systems, elastic resistance, or even an isokinetic unit), the interaction between the patient and therapist, a prominent feature of PNF, provides the greatest amount and variety of sensory input, particularly in the early phases of re-establishing neuromuscular control.

Manual Contacts

The term *manual contact* refers to how and where the therapist's hands are placed on the patient. Whenever possible, manual contacts are placed over the agonist muscle groups or their tendinous insertions. These contacts allow the therapist to apply resistance to the appropriate muscle groups and cue the patient as to the desired direction of movement. For example, if wrist and finger extension is to be resisted, manual

TABLE 6.10 Component Motions of PNF Patterns: Upper and Lower Extremities

Joints or Segments	Diagonal 1: Flexion (D_1Flx)	Diagonal 1: Extension (D_1Ext)	Diagonal 2: Flexion (D_2Flx)	Diagonal 2: Extension (D_2Ext)
UPPER EXTREMITY COMPONENT MOTIONS				
Shoulder	Flexion-adduction-external rotation	Extension-abduction-internal rotation	Flexion-abduction-external rotation	Extension-adduction-internal rotation
Scapula	Elevation, abduction, upward rotation	Depression, adduction, downward rotation	Elevation, abduction, upward rotation	Depression, adduction downward rotation
Elbow	Flexion or extension	Flexion or extension	Flexion or extension	Flexion or extension
Forearm	Supination	Pronation	Supination	Pronation
Wrist	Flexion, radial deviation	Extension, ulnar deviation	Extension, radial deviation	Flexion, ulnar deviation
Fingers and thumb	Flexion, adduction	Extension, abduction	Extension,abduction	Flexion, adduction
LOWER EXTREMITY COMPONENT MOTIONS				
Hip	Flexion-adduction-external rotation	Extension-abduction-internal rotation	Flexion-abduction-internal rotation	Extension-adduction-external rotation
Knee	Flexion or extension	Flexion or extension	Flexion or extension	Flexion or extension
Ankle	Dorsiflexion, inversion	Plantarflexion, eversion	Dorsiflexion, eversion	Plantarflexion, inversion
Toes	Extension	Flexion	Extension	Flexion

contact is on the dorsal surface of the hand and wrist. In the extremity patterns, one manual contact is placed distally (where movement begins). The other manual contact can be placed more proximally, for example, at the shoulder or scapula. Placement of manual contacts is adjusted based on the patient's response and level of control.

Maximal Resistance

The amount of resistance applied during dynamic concentric muscle contractions is the greatest amount possible that still allows the patient to move smoothly and without pain through the available ROM. Resistance should be adjusted throughout the pattern to accommodate strong and weak components of the pattern.

Position and Movement of the Therapist

The therapist remains positioned and aligned along the diagonal planes of movement with shoulders and trunk facing in the direction of the moving limb. Use of effective body mechanics is essential. Resistance should be applied through body weight, not only through the upper extremities. The therapist must use a wide base of support, move with the patient, and pivot over the base of support to allow rotation to occur in the diagonal pattern.

Stretch

Stretch stimulus. The stretch stimulus is the placing of body segments in positions that lengthen the muscles that are to contract during the diagonal movement pattern. For example, prior to initiating D_1Flexion of the lower extremity, the lower limb is placed in D_1Extension.

Rotation is of utmost consideration because it is the rotational component that elongates the muscle fibers and spindles of the agonist muscles of a given pattern and increases the excitability and responsiveness of those muscles. The stretch stimulus is sometimes described as "winding up the part" or "taking up the slack."

Stretch reflex. The stretch reflex is facilitated by a rapid stretch (overpressure) just past the point of tension to an already elongated agonist muscle. The stretch reflex is usually directed to a distal muscle group to elicit a phasic muscle contraction to initiate a given diagonal movement pattern. The quick stretch is followed by sustained resistance to the agonist muscles to keep the contracting muscles under tension. For example, to initiate D_1Flexion of the upper extremity, a quick stretch is applied to the already elongated wrist and finger flexors followed by application of resistance. A quick stretch also can be applied to any agonist muscle group at any point during the execution of a diagonal pattern to further stimulate an agonist muscle contraction or direct a patient's attention to a weak component of a pattern. (See additional discussion of the use of *repeated contractions* in the next section, which describes special PNF techniques.)

PRECAUTION: Use of a stretch reflex, even prior to resisted isometric muscle contractions, is not advisable during the early stages of soft tissue healing after injury or surgery. It is also inappropriate with acute or active arthritic conditions.

Normal Timing

A sequence of distal to proximal, coordinated muscle contractions occurs during the diagonal movement patterns. The distal component motions of the pattern should be completed halfway through the pattern. Correct sequencing of movements promotes neuromuscular control and coordinated movement.

Traction

Traction is the slight separation of joint surfaces, theoretically, to inhibit pain and facilitate movement during execution of the movement patterns.[220,264,279] Traction is most often applied during flexion (antigravity) patterns.

Approximation

The gentle compression of joint surfaces by means of manual compression or weight bearing stimulates co-contraction of agonists and antagonists to enhance dynamic stability and postural control via joint and muscle mechanoreceptors.[220,264,279]

Verbal Commands

Auditory cues are given to enhance motor output. The tone and volume of the verbal commands are varied to help maintain the patient's attention. A sharp verbal command is given simultaneously with the application of the stretch reflex to synchronize the phasic, reflexive motor response with a sustained volitional effort by the patient. Verbal cues then direct the patient throughout the movement patterns. As the patient learns the sequence of movements, verbal cues can be more succinct.

Visual Cues

The patient is asked to follow the movement of a limb to further enhance control of movement throughout the ROM.

Upper Extremity Diagonal Patterns

NOTE: All descriptions for hand placements are for the patient's right (R) upper extremity. During each pattern tell the patient to watch the moving hand. Be sure that rotation shifts *gradually* from internal to external rotation (or vice versa) throughout the ROM. By midrange, the arm should be in neutral rotation. Manual contacts (hand placements) may be altered from the suggested placements as long as contact remains on the appropriate surfaces. Resist all patterns through the full, available ROM.

D_1Flexion VIDEO 6.10

Starting Position (Fig. 6.33 A)

Position the upper extremity in shoulder extension, abduction, and internal rotation; elbow extension; forearm pronation; and wrist and finger extension with the hand about 8 to 12 inches from the hip.

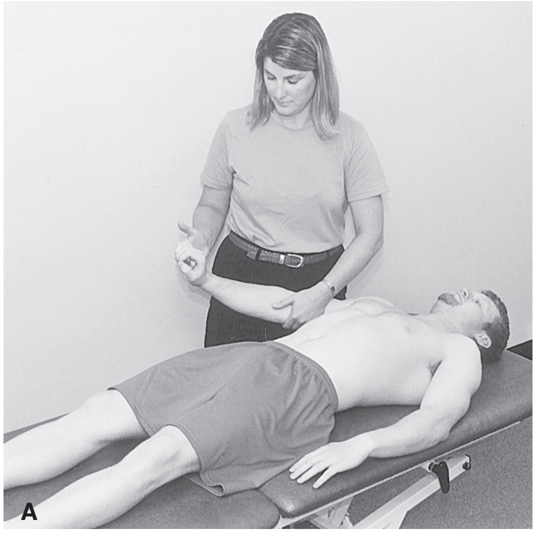

FIGURE 6.33 (A) Starting position and

Hand Placement

Place the index and middle fingers of your (R) hand in the palm of the patient's hand and your left (L) hand on the volar surface of the distal forearm or at the cubital fossa of the elbow.

Verbal Commands

As you apply a quick stretch to the wrist and finger flexors, tell the patient "Squeeze my fingers; turn your palm up; pull your arm up and across your face," as you resist the pattern.

Ending Position (Fig. 6.33 B)

Complete the pattern with the arm across the face in shoulder flexion, adduction, external rotation; partial elbow flexion; forearm supination; and wrist and finger flexion.

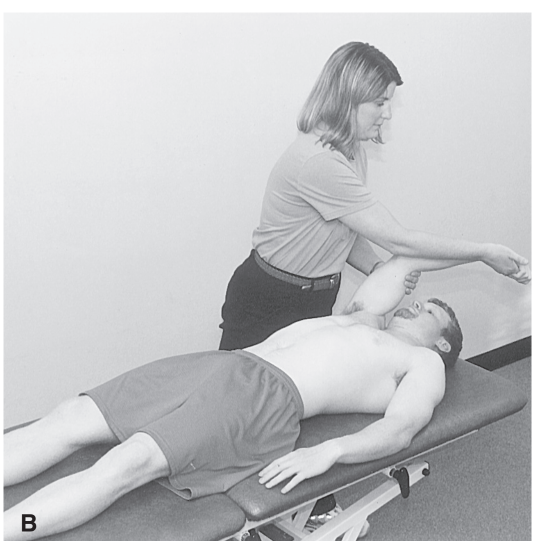

FIGURE 6.33 (B) ending position for D_1 flexion of the upper extremity.

D_1 Extension

Starting Position (Fig. 6.34 A)

Begin as described for completion of D_1 Flexion.

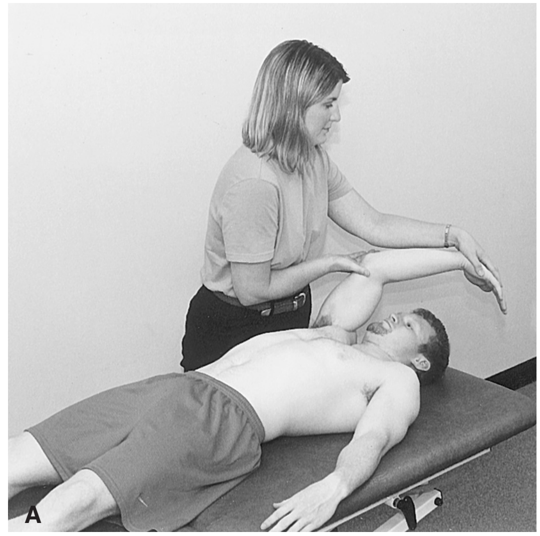

FIGURE 6.34 (A) Starting position and

Hand Placements

Grasp the dorsal surface of the patient's hand and fingers with your (R) hand using a *lumbrical grip*. Place your (L) hand on the extensor surface of the arm just proximal to the elbow.

Verbal Commands

As you apply a quick stretch to the wrist and finger extensors, tell the patient, "Open your hand" (or "Wrist and fingers up"); then "Push your arm down and out."

Ending Position (Fig. 6.34 B)

Finish the pattern in shoulder extension, abduction, internal rotation; elbow extension; forearm pronation; and wrist and finger extension.

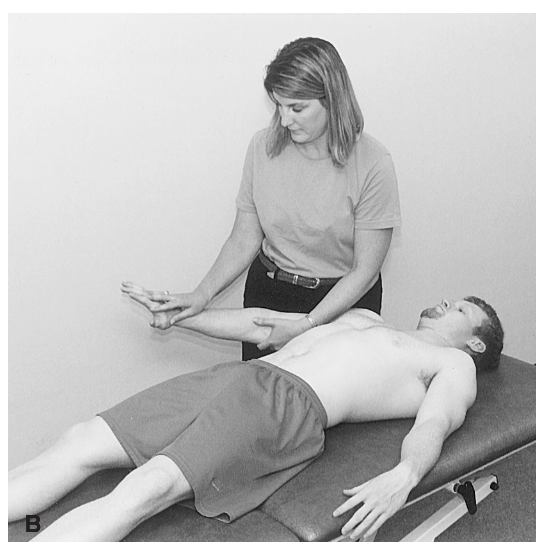

FIGURE 6.34 (B) ending position for D_1 extension of the upper extremity.

D_2Flexion VIDEO 6.11

Starting Position (Fig. 6.35 A)

Position the upper extremity in shoulder extension, adduction, and internal rotation; elbow extension; forearm pronation; and wrist and finger flexion. The forearm should lie across the umbilicus.

FIGURE 6.35 (A) Starting position and

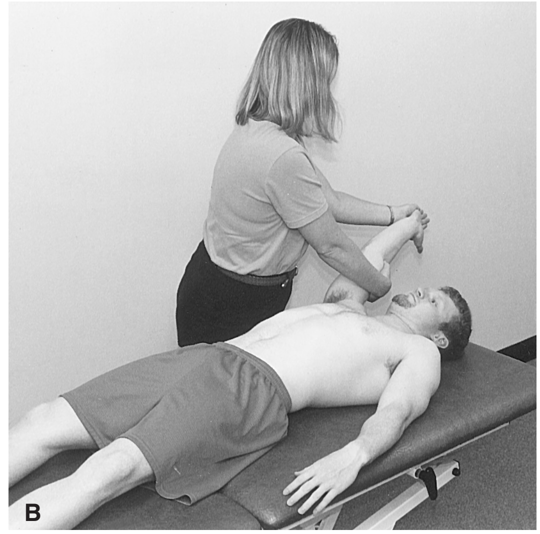

FIGURE 6.35 (B) ending position for D_2 flexion of the upper extremity.

Hand Placement

Grasp the dorsum of the patient's hand with your (L) hand using a lumbrical grip. Grasp the dorsal surface of the patient's forearm close to the elbow with your (R) hand.

Verbal Commands

As you apply a quick stretch to the wrist and finger extensors, tell the patient, "Open your hand and turn it to your face;" "Lift your arm up and out;" "Point your thumb out."

Ending Position (Fig. 6.35 B)

Finish the pattern in shoulder flexion, abduction, and external rotation; elbow extension; forearm supination; and wrist and finger extension. The arm should be 8 to 10 inches from the ear; the thumb should be pointing to the floor.

D_2Extension

Starting Position (Fig. 6.36 A)

Begin as described for completion of D_2Flexion.

Hand Placement

Place the index and middle fingers of your (R) hand in the palm of the patient's hand and your (L) hand on the volar surface of the forearm or distal humerus.

Verbal Commands

As you apply a quick stretch to the wrist and finger flexors, tell the patient, "Squeeze my fingers and pull down and across your chest."

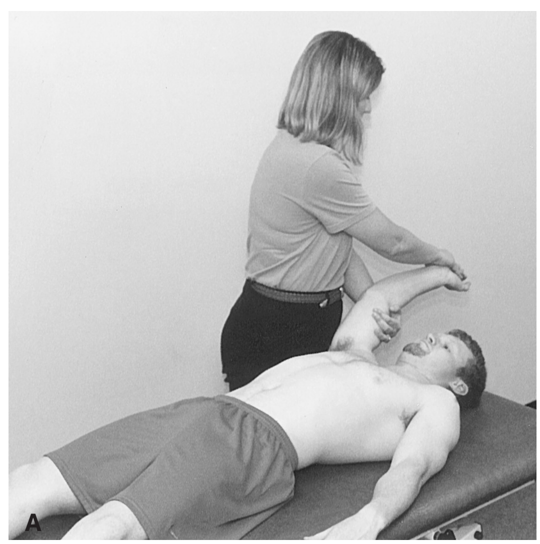

FIGURE 6.36 (A) Starting position and

Ending Position (Fig. 6.36 B)

Complete the pattern in shoulder extension, adduction, and internal rotation; elbow extension; forearm pronation; and wrist and finger flexion. The forearm should cross the umbilicus.

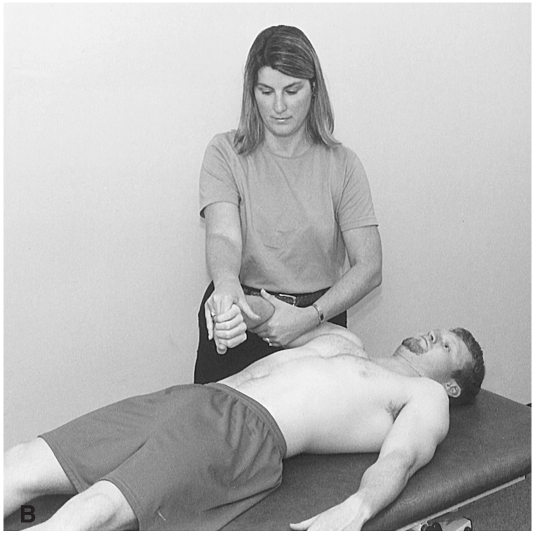

FIGURE 6.36—cont'd (B) ending position for D_2 extension of the upper extremity.

Lower Extremity Diagonal Patterns

NOTE: Follow the same guidelines with regard to rotation and resistance as previously described for the upper extremity. All descriptions of hand placements are for the patient's (R) lower extremity.

D_1Flexion VIDEO 6.12

Starting Position (Fig. 6.37 A)

Position the lower extremity in hip extension, abduction, and internal rotation; knee extension; plantar flexion and eversion of the ankle; and toe flexion.

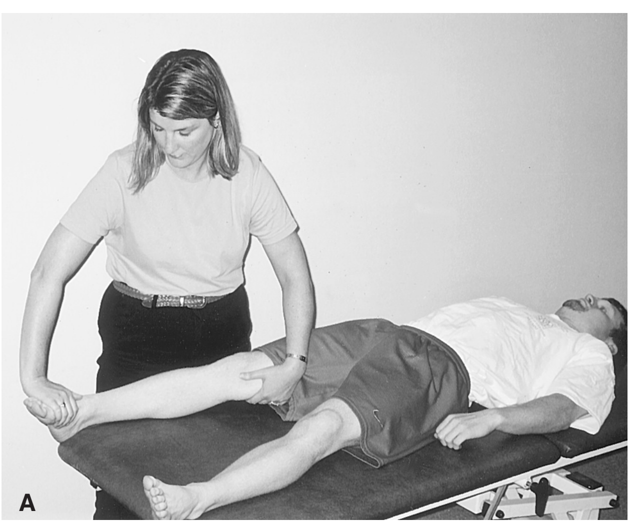

FIGURE 6.37 (A) Starting position and

NOTE: This pattern may also be initiated with the knee flexed and the lower leg over the edge of the table.

Hand Placement

Place your (R) hand on the dorsal and medial surface of the foot and toes and your (L) hand on the anteromedial aspect of the thigh just proximal to the knee.

Verbal Commands

As you apply a quick stretch to the ankle dorsiflexors and invertors and toe extensors, tell the patient, "Foot and toes up and in; bend your knee; pull your leg over and across."

Ending Position (Fig. 6.37 B)

Complete the pattern in hip flexion, adduction, and external rotation; knee flexion (or extension); ankle dorsiflexion and inversion; toe extension. The hip should be adducted across the midline, creating lower trunk rotation to the patient's (L) side.

FIGURE 6.37 (B) ending position for D_1 flexion of the lower extremity.

D_1Extension

Starting Position (Fig. 6.38 A)

Begin as described for completion of D_1Flexion.

Hand Placement

Place your (R) hand on the plantar and lateral surface of the foot at the base of the toes. Place your (L) hand (palm up) at the posterior aspect of the knee at the popliteal fossa.

Verbal Commands

As you apply a quick stretch to the plantarflexors of the ankle and toes, tell the patient, "Curl (point) your toes; push down and out."

Ending Position (Fig. 6.38 B)

Finish the pattern in hip extension, abduction, and internal rotation; knee extension or flexion; ankle plantarflexion and eversion; and toe flexion.

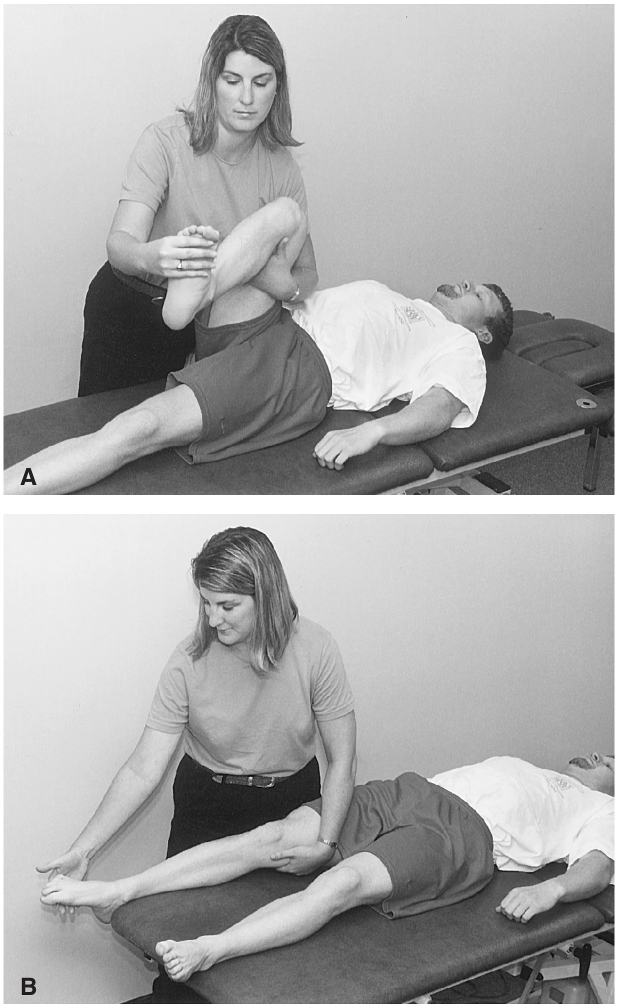

FIGURE 6.38 **(A)** Starting position and **(B)** ending position for D_1 extension of the lower extremity.

D_2Flexion VIDEO 6.13

Starting Position (Fig. 6.39 A)

Place the lower extremity in hip extension, adduction, and external rotation; knee extension; ankle plantarflexion and inversion; and toe flexion.

Hand Placement

Place your (R) hand along the dorsal and lateral surfaces of the foot and your (L) hand on the anterolateral aspect of the thigh just proximal to the knee. The fingers of your (L) hand should point distally.

Verbal Commands

As you apply a quick stretch to the ankle dorsiflexors and evertors and toe extensors, tell the patient, “Foot and toes up and out; lift your leg up and out.”

FIGURE 6.39 **(A)** Starting position and

Ending Position (Fig. 6.39 B)

Complete the pattern in hip flexion, abduction, and internal rotation; knee flexion (or extension); ankle dorsiflexion and eversion; and toe extension.

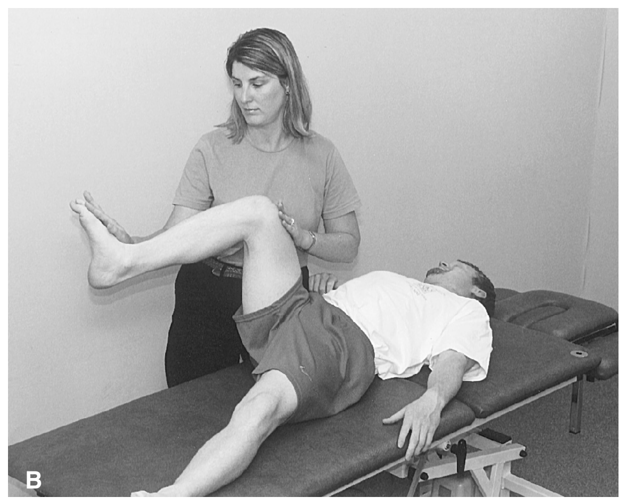

FIGURE 6.39 **(B)** ending position for D_2 flexion of the lower extremity.

D_2Extension

Starting Position (Fig. 6.40 A)

Begin as described for the completion of D_2Flexion.

Hand Placement

Place your (R) hand on the plantar and medial surface of the foot at the base of the toes and your (L) hand at the posteromedial aspect of the thigh, just proximal to the knee.

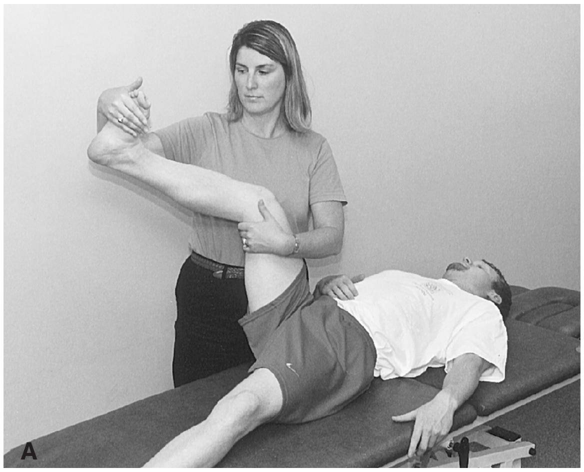

FIGURE 6.40 (A) Starting position and

Verbal Commands

As you apply a quick stretch to the plantarflexors and invertors of the ankle and toe flexors, tell the patient, "Curl (point) your toes down and in; push your leg down and in."

Ending Position (Fig. 6.40 B)

Complete the pattern in hip extension, adduction, and external rotation; knee extension; ankle plantarflexion and inversion; and toe flexion.

FIGURE 6.40 (B) ending position for D_2 extension of the lower extremity.

Specific Techniques with PNF

There are a number of specific techniques that may be used during the execution of a PNF pattern to stimulate weak muscles further and enhance movement or stability. These techniques are implemented selectively by the therapist to evoke the best possible response from the patient and to focus on specific treatment goals.

Rhythmic Initiation

Rhythmic initiation is used to promote the ability to initiate a movement pattern. After the patient voluntarily relaxes, the therapist moves the patient's limb passively through the available range of the desired movement pattern several times so the patient becomes familiar with the sequence of movements within the pattern. Rhythmic initiation also helps the patient understand the rate at which movement is to occur. Practicing assisted or active movements (without resistance) also helps the patient learn a movement pattern.

Repeated Contractions

Repeated, dynamic contractions, initiated with repeated quick stretches followed by resistance, are applied at any point in the ROM to strengthen a weak agonist component of a diagonal pattern.

Reversal of Antagonists

Many functional activities involve quick reversals of the direction of movement. This is evident in diverse activities such as sawing or chopping wood, dancing, playing tennis, or grasping and releasing objects. The reversal of antagonists technique involves stimulation of a weak agonist pattern by first resisting static or dynamic contractions of the antagonist pattern. The reversals of a movement pattern are instituted just before the previous pattern has been fully completed.

There are two categories of reversal techniques available to strengthen weak muscle groups.

Slow reversal. Slow reversal involves dynamic concentric contraction of a stronger agonist pattern immediately followed by dynamic concentric contraction of the weaker antagonist pattern. There is no voluntary relaxation between patterns. This promotes rapid, reciprocal action of agonists and antagonists.

Slow reversal hold. Slow reversal hold adds an *isometric* contraction at the end of the range of a pattern to enhance end-range holding of a weakened muscle. With no period of relaxation, the direction of movement is then rapidly reversed by means of *dynamic* contraction of the agonist muscle groups quickly followed by isometric contraction of those same muscles. This is one of several techniques used to enhance dynamic stability, particularly in proximal muscle groups.

Alternating Isometrics VIDEO 6.14

Another technique to improve isometric strength and stability of the postural muscles of the trunk or proximal stabilizing muscles of the shoulder girdle and hip is alternating isometrics. Manual resistance is applied in a single plane on one side of a body segment and then on the other. The patient is instructed to "hold" his or her position as resistance is alternated from one direction to the opposite direction. No joint movement should occur. This procedure isometrically strengthens agonists and antagonists, and it can be applied to one extremity, to both extremities simultaneously, or to the

trunk. Alternating isometrics can be applied with the extremities in weight-bearing or nonweight-bearing positions.

For example, if a patient assumes a side-lying position, manual contacts are alternately placed on the anterior aspect of the trunk and then on the posterior aspect of the trunk. The patient is told to maintain (hold) the side-lying position as the therapist first attempts to push the trunk in a posterior and then anterior direction (Fig. 6.41 A). Manual contacts are maintained on the patient as the therapist's hands are moved alternately from the anterior to posterior surfaces. Resistance is gradually applied and released. The same can be done unilaterally or bilaterally in the extremities (Fig. 6.41 B).

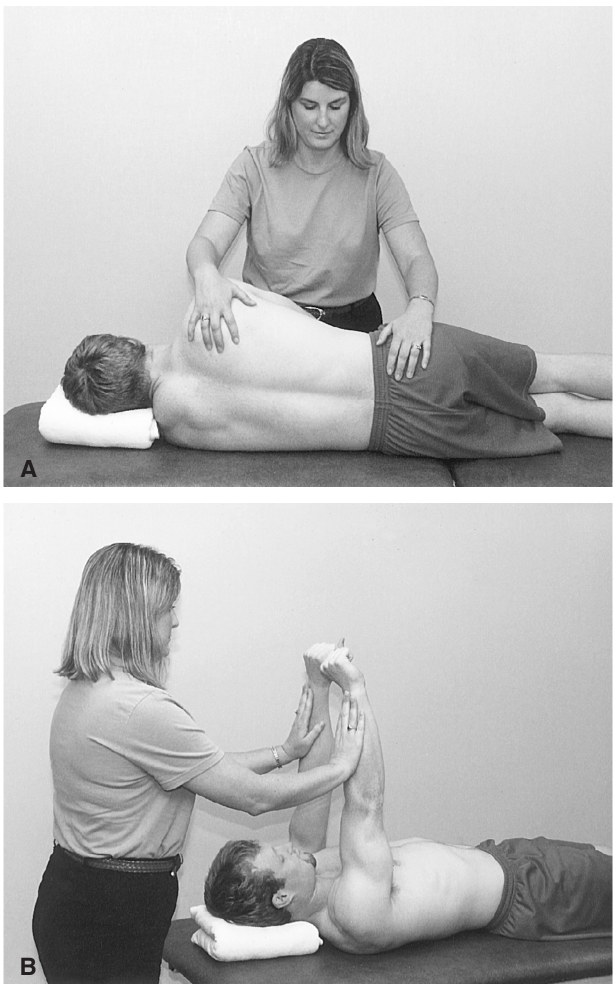

FIGURE 6.41 **(A)** Use of alternating isometrics to improve static strength of the proximal musculature by alternately placing both hands and applying resistance to the anterior aspect of the body and then to the posterior aspect of the body. **(B)** Use of alternating isometrics in the upper extremities.

Rhythmic Stabilization

Rhythmic stabilization is used as a progression of alternating isometrics and is designed to promote stability through co-contraction of the proximal stabilizing musculature of the trunk as well as the shoulder and pelvic girdle regions of the body. Rhythmic stabilization typically is performed in weight-bearing positions to incorporate joint approximation into the procedure, hence further facilitating co-contraction. The therapist applies multidirectional, rather than unidirectional, resistance by placing manual contacts on opposite sides of the body and applying resistance simultaneously in opposite directions as the patient holds the selected position. Multiple muscle groups around joints—most importantly the rotators—must contract to hold the position.

For example, in the selected position, the patient is told to hold that position as one hand pushes against the posterior aspect of the body and the other hand simultaneously pushes against the anterior aspect of the body (Fig. 6.42). Manual contacts are then shifted to the opposite surfaces and isometric holding against resistance is repeated. There is no voluntary relaxation between contractions.

Use of these special techniques, as well as others associated with PNF, gives the therapist a significant variety of manual resistance exercise techniques to increase muscle strength and to promote dynamic stability and controlled mobility as the foundation of and in preparation for initiating task-specific skilled movements in a rehabilitation program.

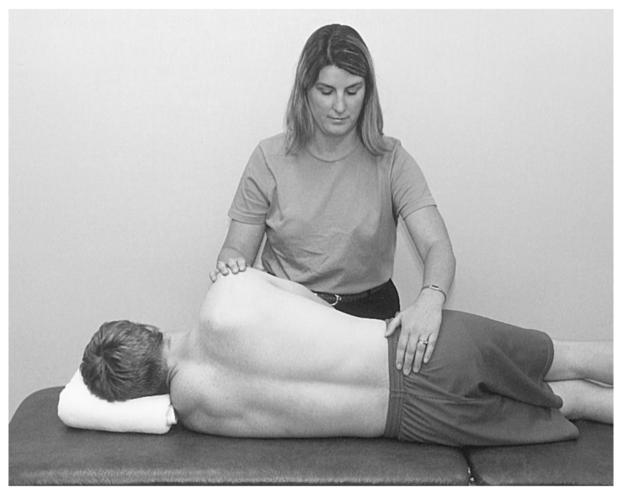

FIGURE 6.42 Use of rhythmic stabilization to improve stability of the trunk by simultaneously applying resistance in opposite directions to the anterior and posterior surfaces of the trunk, emphasizing isometric contractions of the trunk rotators.

Mechanical Resistance Exercise

Mechanical resistance exercise is any form of exercise in which resistance (the exercise load) is applied by means of some type of exercise equipment. Frequently used terms that denote the use of mechanical resistance are *resistance training*, *weight training*, and *strength training*.[6,8-10,18,35]

Mechanical resistance exercise is an integral component of rehabilitation and fitness/conditioning programs for individuals of all ages. However, use of mechanical resistance in an exercise program has some advantages and disadvantages (Box 6.15).

Application in Rehabilitation Programs

Mechanical resistance exercise is commonly implemented in rehabilitation programs to eliminate or reduce deficits in muscular strength, power, and endurance caused by an array of pathological conditions and to restore or improve functional abilities. Guidelines for integration of mechanical resistance exercises into an individualized rehabilitation program for patients with specific conditions are detailed in Chapters 16 through 23.

BOX 6.15 Mechanical Resistance Exercise: Advantages and Disadvantages

Advantages

- Establishes a quantitative baseline measurement of muscle performance against which improvement can be judged.
- Most appropriate during intermediate and advanced phases of rehabilitation when muscle strength is 4/5 or greater or when the strength of the patient exceeds the therapist's strength.
- Provides exercise loads far beyond that which can be applied manually by a therapist to induce a training effect for already strong muscle groups.
- Provides quantitative documentation of incremental increases in the amount of resistance.
  - Quantitative improvement is an effective source of motivation for the patient.
- Useful for improving dynamic or static muscular strength.
- Adds variety to a resistance training program.
- Practical for high-repetition training to improve muscular endurance.
- Some equipment provides variable resistance through the ROM.
- High-velocity resistance training is possible and safe with some forms of mechanical resistance (hydraulic and pneumatic variable resistance machines, isokinetic units, elastic resistance).
  - Potentially better carryover to functional activities than relatively slow-velocity manual resistance exercises.
  - Appropriate for independent exercise in a home program after careful patient education and a period of supervision.

Disadvantages

- Not appropriate when muscles are very weak or soft tissues are in the very early stages of healing, with the exception of some equipment that provides assistance, support, or control against gravity.
- Equipment that provides constant external resistance maximally loads the muscle at only one point in the ROM.
- No accommodation for a painful arc (except with hydraulic, pneumatic, or isokinetic equipment).
- Expense for purchase and maintenance of equipment.
- With free weights and weight machines, gradation in resistance is dependent on the manufacturer's increments of resistance.

Application in Fitness and Conditioning Programs

There is a growing awareness through health promotion and disease prevention campaigns that training with weights or other forms of mechanical resistance is an important component of comprehensive programs of physical activity designed to improve or maintain fitness and health throughout most of the life span. As in rehabilitation programs, resistance training complements aerobic training and flexibility exercises in conditioning and fitness programs. Guidelines for a balanced resistance training program for the healthy, but untrained adult (less than 50 to 60 years of age) recommended by the American College of Sports Medicine[8,10] and the Centers for Disease Control and Prevention.[35] are summarized in Box 6.16.

BOX 6.16 Summary of Guidelines for Resistance Training in Conditioning Programs for Healthy Adults (<50–60 years old)

- Prior to resistance training, perform warm-up activities followed by flexibility exercises.
- Perform dynamic exercises through the full, available, and pain-free ROM and target the major muscle groups of the body (approximately 8–10 muscle groups of the upper and lower extremities and trunk) for total body muscular fitness.
- Balance flexion-dominant (pulling) exercises with extension-dominant (pushing) exercises.
- Include both concentric (lifting) and eccentric (lowering) muscle actions.
- *Intensity:* Perform moderate-intensity (60% to 80% of 1-RM) exercises that allow 8 to 12 repetitions of each exercise per set.
  - Increase intensity gradually (increments of approximately 5%) to progress the program as strength and muscular endurance improve.
- *Sets:* 2 sets, progressing to 4 sets of each exercise.
- *Rest intervals:* 2 to 3 minutes between sets. While resting one muscle group, exercise a different muscle group.
- *Frequency:* two to three times per week.
- Use slow to moderate speeds of movement.
- Use rhythmic, controlled, non-ballistic movements.
- Exercises should not interfere with normal breathing.
- Whenever possible, train with a partner for feedback and assistance.
- Cool-down after completion of exercises.
- After a layoff of more than 1 to 2 weeks, reduce the resistance and volume when reinitiating weight training.

Special Considerations for Children and Older Adults

As noted previously, children and older adults often find it necessary or wish to engage in resistance training either as part of a rehabilitation program to correct impairments and reduce functional limitations or a program of physical activity designed to improve fitness, reduce health-related risk factors, or enhance physical performance. Resistance training can be safe and effective if exercise guidelines are modified to meet the unique needs of these two groups.

Children and Resistance Training

Until the past decade or two, health professionals have been reluctant to support preadolescent youth participation in resistance training as a part of fitness programs because of concerns about possible adverse stress and injury to the immature musculoskeletal system—in particular, growth-plate injuries and avulsion fractures. Furthermore, a common assumption was that the benefits of resistance training were questionable in children.[27,89,90,93]

There is now growing awareness that children can achieve health-related benefits from resistance training and can safely engage in weight-training programs if designed appropriately and closely supervised.[7,8,36,119,266] Use of body weight as a source of resistance and equipment specifically designed to fit a child contributes to program safety (Fig. 6.43).

Training-induced strength gains in prepubescent children have been documented,[90,92,297] but sport-related injury prevention remains of questionable benefit.[90,297] As with adults, information on the impact of strength training on the enhancement of functional motor skills is limited.

FIGURE 6.43 Youth resistance training on Kids-N-Motion® equipment (Triceps-Dip), specifically designed and sized for a child's use. *(Courtesy of Youth Fitness International, Moncks Corner, SC; www.youthfit.com/.)*

FOCUS ON EVIDENCE

Research has shown that, although some acute and chronic responses of children to exercise are similar to those of adults, other responses are quite different. For example, because of an immature thermo-regulation system, children dissipate body heat less easily, fatigue more quickly, and therefore, need longer rest periods than young adults to recover from exercise.[79,297] Such differences in response to resistance exercise must be addressed when designing and implementing strength training programs for children.

Accordingly, the American Academy of Pediatrics,[6] the American College of Sports Medicine,[8] and The Centers for Disease Control and Prevention,[36] support youth involvement in resistance training—but only if a number of special guidelines and precautions are consistently followed. Although the risk of injury from resistance training is quite low if performed at an appropriate intensity and volume,[93,266] exercise-induced soft tissue or growth plate injuries have been noted if guidelines and precautions are not followed. Guidelines and special considerations for resistance training in children as a component of regular physical activity are summarized in Box 6.17.[6,8,36,90,91,119,266] Consistent with adult guidelines, a balanced program of dynamic exercise for major muscle groups includes warm-up and cool-down periods.

Older Adults and Resistance Training

It is well known that muscle performance diminishes with age,[107,185,278,295] and deficits in muscle strength, power, and endurance are associated with a higher incidence of activity limitations and participation restrictions (functional limitations and disability).[145,278] The extent to which decreasing muscle strength is caused by the normal aging process versus a sedentary lifestyle or an increasing incidence of age-related diseases, such as hypertension and osteoarthritis, is not clear.

A major goal of resistance training in older adults is to maintain or improve their levels of functional independence[3,8,39,263,278] and reduce the risk of age-related diseases.[8,9,278] As with young and middle-aged adults, older adults (older than age 60 to 65) benefit from regular physical activity that includes aerobic activities, flexibility exercises, and resistance training. Even in previously sedentary older adults or frail elderly patients, a program of weight training has resulted in training-induced gains in muscle strength.*

Resistance training also has been shown to improve other parameters of physical function, such as balance, speed of walking, and the ability to rise from a chair and minimize the incidence of falls.[3,40,97,145,209,263,286]

*39,40,47,120,145,177,202,246,263,265

BOX 6.17 Resistance Training for Children: Guidelines and Special Considerations

- No formal resistance training for children younger than 6 to 7 years of age; age-appropriate physical activity through organized and free play recommemded.
- At age 6 to 7, introduce the *concept* of an exercise session; encourage 60 or more minutes of moderate-intensity physical activity daily or at least 3 to 4 days per week; focus on aerobic activities (active exercises without weights).
  - Include weight-bearing exercises, such as push-ups and jumping activities for bone strengthening 3 days per week.
  - Emphasize a variety of short-duration, play-oriented exercises to prevent boredom, overheating, and muscle fatigue.
  - As a small portion of daily physical activity, perform muscle-strengthening exercises against the resistance of body weight (sit-ups, chin-ups). Postpone including exercises with light weights added for several years.
- When introducing weight-training in the prepubescent years:
  - Maintain *close* and *continuous supervision* by trained personnel or a parent who has received instruction.
  - Always perform warm-up activities for at least 5 to 10 minutes before initiating resistance exercises.
  - Focus on proper form, exercise technique, and safety (alignment, stabilization, controlled/nonballistic movements).
  - Emphasize low-intensity exercise throughout childhood to avoid potential injury to a child's growing skeletal system and to joints and supportive soft tissues.
  - Emphasize adequate hydration.
- *Intensity:* Select low exercise loads that allow 8 to 15[9,90] repetitions.
  - Progress gradually to moderate-intensity (60% to 80% of an estimated 1-RM) exercise loads.
  - Do not use near-maximal or maximal exercise loads or participate in power lifting or body building until physical and skeletal maturity has been reached.
- *Sets and rest intervals:* Initially perform only one set, progressing to 2 to 2 sets of each exercise; rest at least 3 minutes between sets of exercises.
- *Frequency:* Limit the frequency of resistance training to no more than two sessions per week.
- Emphasize multi-joint, combined movements.
- Avoid or limit the use of eccentric resistance exercises.
- Initially progress resistance training by increasing repetitions, not resistance, or by increasing the total number of exercises. Later, increase weight by no more than 5% at a time.[8,90]
- Use properly fitting equipment that is designed or can be adapted for a child's size. Many weight machines cannot be adequately adjusted to fit a child's stature.

Although many of the guidelines for resistance training that apply to young and middle-aged adults (see Box 6.16) are applicable to healthy older adults, in general, resistance training for older adults should be more closely supervised and initially less rigorous than for younger adults.[8,9,37,295] Accordingly, impaired balance, age-related postural changes, and poor vision that can compromise safety must be addressed if present. Also, because of age-related changes in connective tissue, there is a higher incidence of DOMS and greater muscle fiber damage in older versus young adults after heavy-resistance, high-volume strength training.[233]

Guidelines for safe but effective resistance training for older adults are listed in Box 6.18.[8,9,37,288] As with young adult guidelines, resistance training should be coupled with aerobic

BOX 6.18 Resistance Training for Older Adults (>60–65 Years): Guidelines and Special Considerations

- Secure approval to initiate exercise from the participant's physician.
- Institute close supervision during the early phase of training to ensure safety.
- Monitor vital signs, particularly when the program is progressed.
- Perform at least 5 to 10 minutes of warm-up activities before each session of resistance exercises.
- *Intensity:* Begin resistance training with low (40% to 60% of an estimated 1-RM) to moderate (60% to 80%) levels of resistance (at a level that permits 10 to 15 repetitions).
  - Progress by increasing repetitions; later, increase resistance by small increments.
  - Keep the intensity of eccentric exercises in the low to moderate range to reduce the risk of soft tissue damage.
  - Throughout the program avoid high-load resistance exercises to reduce excessive stresses on joints.
  - Reduce the intensity and volume of weight training by 50% after a 1- to 2-week layoff.
- *Repetitions and sets:* Perform 8 to 12 repetitions of each exercise for at least one set, gradually progressing to 2 or 3 sets.
- *Rest intervals:* Allowing a 48-hour rest interval between sessions.
- *Frequency:* Perform resistance training two or more day a week.
- Include low-impact weight-bearing exercises (partial lunges, squats, step-ups/step downs) against the resistance of body weight.
- Exercise all major muscle groups of the upper and lower extremities and trunk.
- Modify exercises for age-related postural changes, such as excessive kyphosis, that can alter the biomechanics of an exercise.
- Avoid flexion-dominant resistance training that could emphasize postural changes.
- When possible, use weight machines that allow the participant to perform exercises in a seated position to avoid loss of balance.

training and flexibility exercises, and balance activities. Proper warm-up and cool-down periods, a balanced program of dynamic exercises, controlled movements, and proper form and technique are equally important for older adults.

Selected Resistance Training Regimens

For the past 50 to 60 years practitioners and researchers alike in rehabilitation and fitness settings have taken great interest in resistance exercise and functional training. As a result, many systems of exercise have been developed to improve muscle strength, power, and endurance. All of these systems are based on the overload principle, and most use some form of mechanical resistance to load the muscle. The driving force behind the development of these regimens seems to be to design the "optimal"—that is, the most effective and efficient—method to improve muscular performance and functional abilities.

Several frequently used regimens of resistance training for rehabilitation and for fitness and conditioning programs—PRE, circuit weight training, and velocity spectrum isokinetic training—are presented in this section. Some approaches to advanced training, such as plyometric exercises (stretch-shortening drills) to develop muscle power, are presented in Chapter 23.

Progressive Resistance Exercise

PRE is a system of dynamic resistance training in which a constant external load is applied to the contracting muscle by some mechanical means (usually a free weight or weight machine) and incrementally increased. The RM is used as the basis for determining and progressing the resistance.

FOCUS ON EVIDENCE

The results of countless studies have demonstrated that PRE improves the force-generating capacity of muscle that potentially can carry over to improvement in physical performance. It is important to note that the participants in many of these studies have been young, healthy adults, rather than patients with structural and functional impairments associated with injury and disease.

However a systematic review of the literature[267] in 2005 indicated that PRE also was beneficial for patients with a variety of pathological conditions including musculoskeletal injuries, osteoarthritis, osteoporosis, hypertension, adult-onset (type II) diabetes, and chronic obstructive pulmonary disease. Specific findings of some of the studies identified in this systematic review are presented in later chapters of this textbook.

Delorme and Oxford Regimens

The concept of PRE was introduced over 60 years ago by DeLorme,[64,65] who originally used the term *heavy resistance training*[64] and later *load-resisting exercise*[65] to describe a new system of strength training. DeLorme proposed and studied the use of three sets of a percentage of a 10-RM with progressive loading during each set. Other investigators[304] developed a regimen, the Oxford technique, with regressive loading in each set (Table 6.11).

The DeLorme technique builds a warm-up period into the protocol, whereas the Oxford technique diminishes the resistance as the muscle fatigues. Both regimens incorporate a rest interval between sets; both increase the resistance incrementally over time to apply progressive overload; and both have been shown to result in training-induced strength gains.

FOCUS ON EVIDENCE

In a randomized study comparing the DeLorme and Oxford regimens, no significant difference was found in adaptive strength gains in the quadriceps muscle group in older adults after a 9-week exercise program.[99]

Since the DeLorme and Oxford systems of training were first introduced, numerous variations of PRE protocols have been proposed and studied to determine an optimal intensity of resistance training, optimal number of repetitions and sets, optimal frequency, and optimal progression of loading. In reality, an ideal combination of these variables does not exist. Extensive research has shown that many combinations of exercise load, repetitions and sets, frequency, and rest intervals significantly improve strength.[18,103,169] Typical PRE programs produce training-induced strength gains using 2 to 3 sets of 6 to 12 repetitions of a 6- to 12-RM.[10,18,103,168,169] This gives a therapist wide latitude when designing an effective weight-training program.

DAPRE Regimen

Knowing when and by how much to increase the resistance in a PRE program to overload the muscle progressively is often

TABLE 6.11 Comparison of Two PRE Regimens

DeLorme Regimen	Oxford Regimen
Determination of a 10-RM	Determination of a 10-RM
10 reps @ 50% of the 10-RM	10 reps @ 100% of the 10-RM
10 reps @ 75% of the 10-RM	10 reps @ 75% of the 10-RM
10 reps @ 100% of the 10-RM	10 reps @ 50% of the 10-RM

imprecise and arbitrary. A common guideline is to increase the weight by 5% to 10% when all prescribed repetitions and sets can be completed easily without significant fatigue. The Daily Adjustable Progressive Resistive Exercise (DAPRE) technique[163,164] is more systematic and takes into account the different rates at which individuals progress during rehabilitation or conditioning programs. The system is based on a 6-RM working weight (Table 6.12). The adjusted working weight, which is based on the maximum number of repetitions possible using the working weight in Set #3 of the regimen, determines the working weight for the next exercise session (Table 6.13).

NOTE: It should be pointed out that the recommended increases or decrease in the adjusted working weight are based on progressive loading of the quadriceps muscle group.

Circuit Weight Training

Another system of training that employs mechanical resistance is *circuit weight training*.[20,31,169] A pre-established sequence (circuit) of continuous exercises is performed in succession at individual exercise stations that target a variety of major muscle groups (usually 8 to 12) as an aspect of total body conditioning. An example of a circuit weight training sequence is shown in Box 6.19.

BOX 6.19 Example of a Resistance Training Circuit

Station #1: Bench press → #2: Leg press or squats → #3: Sit-ups → #4: Upright rowing → #5: Hamstring curls → #6: Prone trunk extension → #7: Shoulder press → #8: Heel raises → #9: Push-ups → #10: Leg lifts or lowering

TABLE 6.12 DAPRE Technique

Sets	Repetitions	Amount of Resistance
1	10	50% 6-RM*
2	6	75% 6-RM
3	Maximum possible	100% 6-RM
4	Maximum possible	100% adjusted working weight**

*6 RM = working weight
**See Table 6.13 for calculation of the adjusted working weight.

TABLE 6.13 Calculation of the Adjusted Working Weight for the DAPRE Regimen

Adjustment of Working Weight		
Repetitions in Set 3	Set 4	Next exercise session 3
0–2	↓ 5–10 lb	↓ 5–10 lb
3–4	↓ 0–5 lb	Same weight
5–6	Keep same weight	↑ 5–10 lb
7–10	↑ 5–10 lb	↑ 5–15 lb
11 or more	↑ 10–15 lb	↑ 10–20 lb

Each resistance exercise is performed at an exercise station for a specified number of repetitions and sets. Typically, repetitions are higher and intensity (resistance) is lower than in other forms of weight training. For example, two to three sets of 8 to 12 repetitions at 90% to 100% 10-RM or 10 to 20 repetitions at 40% to 50% 1-RM are performed,[20,192] with a minimum amount of rest (15 to 20 seconds) between sets and stations. The program is progressed by increasing the number of sets or repetitions, the resistance, the number of exercise stations, and the number of circuit revolutions.

Exercise order is an important consideration when setting up a weight training circuit.[18,31,168] Exercises with free weights or weight machines should alternate among upper extremity, lower extremity, and trunk musculature and between muscle groups involved in pushing or pulling actions. This enables one muscle group to rest and recover from exercise while exercising another group and therefore, minimizes muscle fatigue. Ideally, larger muscle groups should be exercised before smaller muscle groups. Multijoint exercises that recruit multiple muscle groups should be performed before exercises that recruit an isolated muscle group to minimize the risk of injury from fatigue.

Isokinetic Regimens

It is well established that isokinetic training improves muscle performance. Its effectiveness in carryover to functional tasks is less clear. Studies support[85,201] and refute[126,230] that isokinetic training improves function. Ideally, when isokinetic training is implemented in a rehabilitation program, to have the most positive impact on function it should be performed at velocities that closely match or at least approach the expected velocities of movement of specific functional tasks. Because many functional movements occur at a variety of medium to fast speeds, isokinetic training typically is performed at medium and fast velocities.[5,57,62,83]

Current isokinetic technology makes it possible to approximate training speeds to velocities of movement during some lower extremity functions, such as walking.[57,299] In the upper extremities, this is far less possible. Some functional movements in the upper extremities occur at exceedingly rapid velocities (e.g., more than 1000° per second for overhead throwing), which far exceed the capabilities of isokinetic dynamometers.[83]

It is also widely accepted that isokinetic training is relatively speed-specific, with only limited transfer of training

(physiological overflow causing improvements in muscle performance at speeds other than the training speed).[149,273] Therefore, *speed-specific isokinetic training,* similar to the velocity of a specific functional task, is advocated.[5,59,83]

Velocity Spectrum Rehabilitation

To deal with the problem of limited physiological overflow of training effects from one training velocity to another, a regimen called *velocity spectrum rehabilitation* (VSR) has been advocated.[57,83,103] With this system of training, exercises are performed across a range of velocities.[252]

NOTE: The guidelines for VSR that follow are for *concentric* isokinetic training. General guidelines for eccentric isokinetics are identified at the conclusion of this section.

Selection of training velocities. Typically, medium (60° or 90° to 180°/sec) and fast (180° to 360°/sec) angular velocities are selected. Although isokinetic units are designed for testing and training at velocities faster than 360° per second, the fastest velocities usually are not used for training. This is because the limb must accelerate to the very fast, preset speed before encountering resistance from the torque arm of the dynamometer. Hence, the contracting muscles are resisted through only a small portion of the ROM.

It has been suggested that the effects of isokinetic training (improvements in muscle strength, power, or endurance) carry over only 15° to 30° per second from the training velocity.[57,149] Therefore, some VSR protocols use 30° per second increments for medium and fast velocity training. Of course, if a patient trains at medium and fast velocities (from 60° or 90° to 360°/sec) in one exercise session, this strategy necessitates nine different training velocities, giving rise to a time-consuming exercise session for one agonist/antagonist combination of muscle groups. A more common protocol is to use as few as three training velocities.[5,83,252]

Repetitions, sets, and rest. A typical VSR protocol might have the patient perform one or two sets of 8 to 10 or as many as 20 repetitions of agonist/antagonist muscle groups (reciprocal training) at multiple velocities.[5,57,83] For example, at medium velocities (between 90° and 180°/sec) training could occur at 90°, 120°, 150°, and 180° per second. A second series would then be performed at decreasing velocities—180°, 150°, 120°, and 90° per second. Because many combinations of repetitions, sets, and different training velocities lead to improvement in muscle performance, the therapist has many options when designing a VSR program. A 15- to 20-second rest between sets and a 60-second rest between exercise velocities has been recommended.[257] The recommended frequency for VSR is a maximum of three times per week.[5]

Intensity. Submaximal effort is used for a brief warm-up period on the dynamometer. However, this is not a replacement for a more general form of upper or lower body warm-up exercises, such as cycling or upper-extremity ergometry. When training to improve endurance, exercises are carried out at a submaximal intensity (effort) but at a maximal intensity to improve strength or power.

During the early stages of isokinetic training, it is useful to begin with submaximal isokinetic exercise at medium and slow velocities so the patient gets the "feel" of the isokinetic equipment and at the same time protects the muscle. As the program progresses, it is usually safe for the patient to exert maximum effort can be exerted at medium speeds. Slow-velocity training is eliminated when the patient begins to exert maximum effort. During the advanced phase of rehabilitation, training with maximum-effort at fast velocities is emphasized, so long as exercises are pain-free.[62] Additional aspects to a progression of isokinetic training regimens include short-arc to full-arc exercises (if necessary) and concentric to eccentric movements.[62]

PRECAUTION: Training with maximum effort at slow velocities is rarely indicated because of the excessive shear forces produced across joint surfaces.[57,83]

Eccentric Isokinetic Training: Special Considerations

As isokinetic technology evolved over several decades, eccentric isokinetic training became possible, but few guidelines for eccentric isokinetic training and evidence of their efficacy are available. Guidelines developed to date are primarily based on clinical opinion or anecdotal evidence. Key differences in eccentric versus concentric isokinetic guidelines (intensity, repetitions, frequency, rest) are listed in Box 6.20. Several resources describe pathology-specific guidelines for eccentric isokinetic training based on clinical experience.[5,57,83,121,122]

PRECAUTIONS: Eccentric isokinetic training is appropriate only during the final phase of a rehabilitation program to continue to challenge individual muscle groups when isolated deficits in strength and power persist. Because of the robotic nature of eccentric isokinetic training, medium rather than fast

BOX 6.20 Key Differences in Eccentric Versus Concentric Isokinetic Training

Eccentric isokinetic exercise is:

- Introduced only *after maximal* effort concentric isokinetic exercise can be performed without pain.
- Implemented only after functional ROM has been restored.
- Performed at slower velocities across a narrower velocity spectrum than concentric isokinetic exercise—usually between 60° and 120°/sec per second for the general population and up to 180°/sec for athletes.
- Carried out at submaximal levels for a longer time frame to avoid extensive torque production and lessen the risk of DOMS.
- Most commonly performed in a continuous concentric-eccentric pattern for a muscle group during training, whereas concentric isokinetics involves reciprocal training of agonist/antagonist muscle groups.

training velocities are considered safer. A sudden, rapid, motor-driven movement of the dynamometer's torque arm against a limb could injure healing tissue.

Equipment for Resistance Training

There seems to be an almost limitless selection of exercise equipment on the market that is designed for resistance training. The equipment ranges from simple to complex, compact to space-consuming, and inexpensive to expensive. An assortment of simple but versatile handheld and cuff weights or elastic resistance products is useful in clinical and home settings, whereas multiple pieces of variable resistance equipment may be useful for advanced-level resistance training. The literature distributed by manufacturers, product demonstrations at professional meetings, and studies of these products reported in the research literature are the main sources of information about new products on the market.

Although most equipment is *load resisting* (augments the resistance of gravity), a few pieces of equipment can be adapted to be *load assisting* (eliminates or diminishes the resistance of gravity) to improve the strength of weak muscles. Equipment can be used for static or dynamic, concentric or eccentric, and open-chain or closed-chain exercises to improve muscular strength, power, or endurance, neuromuscular stability or control, as well as cardiopulmonary fitness.

In the final analysis, the choice of equipment depends primarily on the individual needs, abilities, and goals of the person using the equipment. Other factors that influence the choice of equipment are the *availability*; the *cost* of purchase or maintenance by a facility or a patient; the *ease of use* (application or setup) of the equipment; the *versatility* of the equipment; and the *space requirements* of the equipment. Once the appropriate equipment has been selected, its safe and effective use is the highest priority. General principles for use of equipment are listed in Box 6.21.

Free Weights and Simple Weight-Pulley Systems

Types of Free Weights

Free weights are graduated weights that are handheld or applied to the upper and lower extremities or trunk. They include commercially available dumbbells, barbells, weighted balls (Fig. 6.44), cuff weights, weighted vests, and even sandbags. Free weights also can be fashioned for a home exercise program from readily available materials and objects found around the home.

BOX 6.21 General Principles for the Selection and Use of Equipment

- Base the selection of equipment on a comprehensive examination and evaluation of the patient.
- Determine when in the exercise program the use of equipment should be introduced and when it should be altered or discontinued.
- Determine if the equipment could or should be set up and used independently by a patient.
- Teach appropriate exercise form and technique with the equipment before adding resistance.
- Teach and supervise the application and use of the equipment before allowing a patient to use the equipment independently.
- Adhere to all safety precautions when applying and using the equipment.
  - Be sure all attachments, cuffs, collars, and straps are securely fastened and that the equipment is appropriately adjusted to the individual patient prior to the exercise.
  - Apply padding for comfort, if necessary, especially over boney prominences. Stabilize or support appropriate structures to prevent unwanted movement and undue stress on body parts.
  - If exercise machines are used independently, be certain that set-up and safety instructions are clearly illustrated and affixed directly to the equipment.
- If compatible with the selected equipment, use range-limiting attachments if ROM must be restricted to protect healing tissues or unstable structures.
- If the patient is using the equipment in a home program, give explicit instructions on how, when, and to what extent to change or adapt the equipment to provide a progressive overload.
- When making a transition from use of one type of resistance equipment to another, be certain that the newly selected equipment and method of set-up initially provides a similar level of torque production to the equipment previously employed to avoid insufficient or excessive loads.
- When the exercise has been completed:
  - Disengage the equipment and leave it in proper condition for future use.
  - Never leave broken or potentially hazardous equipment for future use.
- Set up a regular routine of maintenance, replacement, or safety checks for all equipment.

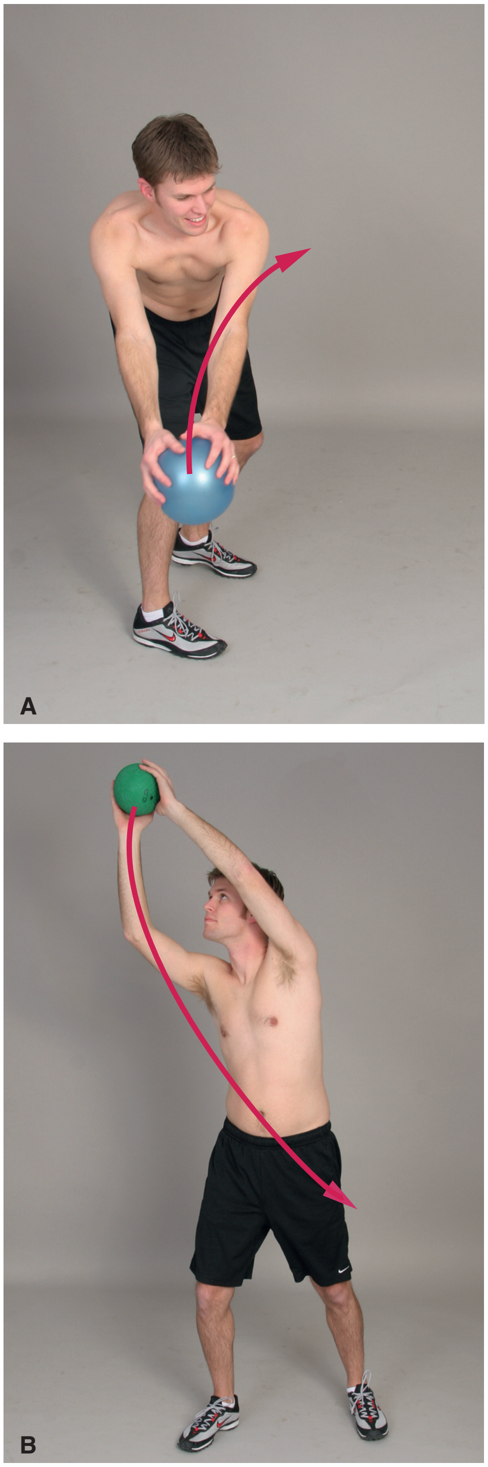

FIGURE 6.44 (A & B) Holding a weighted ball while performing combined patterns of movement provides resistance to upper extremity and trunk muscles and augments the resistance of body weight to lower extremity muscle groups during weight-bearing activities.

Simple Weight-Pulley Systems

Free-standing or wall-mounted simple weight-pulley systems with weight-plates are commonly used for resisted upper and lower extremity or trunk exercises (Fig. 6.45). Permanent or interchangeable weights are available. Permanent weights are usually stacked with individual weight-plates of 5- to 10-pound increments that can be easily adjusted by changing the placement of a single weight key or pin.

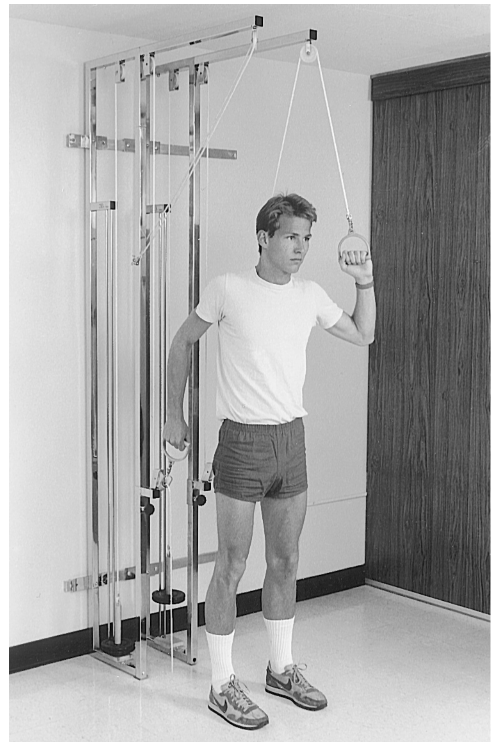

FIGURE 6.45 Multi-Exercise Pulley Unit can be used to strengthen a variety of muscle groups. *(Courtesy of N–K Products Company, Inc., Soquel, CA.)*

NOTE: The simple weight-pulley systems described here are those that impose a relatively constant (fixed) load. Variable resistance weight machines, some of which incorporate pulleys into their designs, are discussed later in this section.

Characteristics of Free Weights and Simple Weight-Pulley Systems

Free weights and weight-pulley systems impose a constant load. The weight selected, therefore, maximally challenges the contacting muscle at only one portion of the ROM when a patient is in a particular position. The weight that is lifted or lowered can be no greater than what the muscle can control at the point in the ROM at which the load provides the maximum torque. In addition, there is no accommodation for a painful arc.

When using free weights, it is possible to vary the point in the ROM at which the maximum exercise load is experienced by changing the patient's position with respect to gravity or the direction of the resistance load. For example, shoulder flexion may be resisted with the patient standing or supine and holding a weight in the hand.

- *Patient position:* standing (Fig. 6.46)—Maximum resistance is experienced and maximum torque is produced when the shoulder is at 90° of flexion. Zero torque is produced when

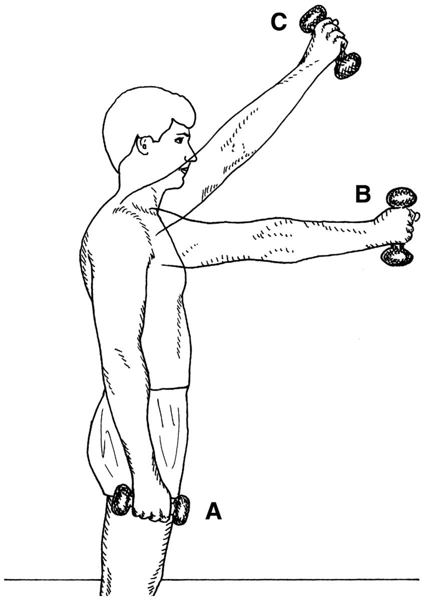

FIGURE 6.46 When the patient is standing and lifting a weight: **(A)** Zero torque is produced in the shoulder flexors when the shoulder is at 0° of flexion. **(B)** Maximum torque is produced when the shoulder is at 90° of flexion. **(C)** Torque again decreases as the arm moves from 90° to 180° of shoulder flexion.

the shoulder is at 0° of flexion. Torque again decreases as the patient lifts the weight from 90° to 180° of flexion. In addition, when the weight is at the side (in the 0° position of the shoulder), it causes traction force on the humerus; when overhead, it causes compression force through the upper extremity.

- *Patient position:* supine (Fig. 6.47)—Maximum resistance is experienced and maximum torque is produced when the shoulder is at 0° of flexion. Zero torque is produced at 90° of shoulder flexion. In this position the entire load creates a compression force. The shoulder flexors are not active between 90° and 180° of shoulder flexion. Instead, the shoulder extensors must contract eccentrically to control the descent of the arm and weight.

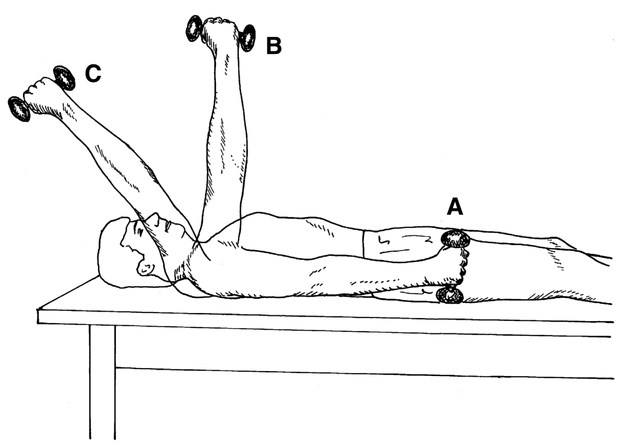

FIGURE 6.47 When the patient is supine and lifting a weight: **(A)** Maximum torque is produced at 0° of shoulder flexion. **(B)** Zero torque is produced at 90° of shoulder flexion. **(C)** The shoulder extensors are active and contract eccentrically against resistance from 90° to 180° of shoulder flexion.

The therapist must determine at which portion of the patient's ROM maximum strength is needed and must choose the optimum position in which the exercise should be performed to gain maximum benefit from the exercise.

Simple weight-pulley systems provide maximum resistance when the angle of the pulley is at right angles to the moving bone. As the angle of the pulley becomes more acute, the load creates more compression through the moving bones and joints and less effective resistance.

Unlike many weight machines, neither free weights nor pulleys provide external stabilization to guide the moving segment or restrict ROM. When a patient lifts or lowers a weight to and from an overhead position, muscles of the scapula and shoulder abductors, adductors, and rotators must synergistically contract to stabilize the arm and keep it aligned in the correct plane of motion. The need for concurrent contraction of adjacent stabilizing muscle groups can be viewed as an advantage or disadvantage. Because muscular stabilization is necessary to control the plane or pattern of movement, less resistance can be controlled with free weights than with a weight machine during the same movement pattern.

Advantages and Disadvantages of Free Weights and Simple Weight-Pulley Systems

- Exercises can be set up in many positions, such as supine, side-lying, or prone in bed or on a cart, sitting in a chair or on a bench, or standing. Many muscle groups in the extremities and trunk can be strengthened by simply repositioning the patient.
- Free weights and simple weight-pulley systems typically are used for dynamic, nonweight-bearing exercises but also can be set up for isometric exercise and resisted weight-bearing activities.
- Stabilizing muscle groups are recruited; however, because there is no external source of stabilization and movements must be controlled entirely by the patient, it may take more time for the patient to learn correct alignment and movement patterns.
- Many movement patterns are possible, incorporating single plane or multiplanar motions. An exercise can be highly specific to one muscle or generalized to several muscle groups. Movement patterns that replicate functional activities can be resisted.
- If a large enough assortment of graduated free weights is available, resistance can be increased by very small increments, as little as 1 pound at a time. The weight plates of pulley systems have larger increments of resistance, usually a minimum of 5 pounds per plate.
- Most exercises with free weights and weight-pulley systems must be performed slowly to minimize acceleration and momentum and prevent uncontrolled, end-range movements that could compromise patient safety. It is thought that the use of exclusively slow movements during

strengthening activities has less carryover to many daily living activities than the incorporation of slow- and fast-velocity exercises into a rehabilitation program. However, a weighted ball can be used with catching and throwing exercises as part of plyometric training during the advanced phase of upper extremity rehabilitation (see Chapter 23).

- Free weights with interchangeable disks, such as a barbell, are versatile and can be used for patients with many different levels of strength, but they require patient or personnel time for proper assembly.
- Bilateral lifting exercises with barbell weights often require the assistance of a spotter to ensure patient safety, thus increasing personnel time.

Variable Resistance Units

Variable resistance exercise equipment falls into two broad categories: specially designed weight-cable (weight-pulley) machines and hydraulic and pneumatic units. Both categories of equipment impose a variable load on the contracting muscles consistent with the changing torque-producing capabilities of the muscles throughout the available ROM.

Variable Resistance Weight-Cable Systems

Variable resistance weight-cable machines (Fig. 6.48) use a cam in their design. The cam (an elliptical or kidney-shaped disk) in the weight-cable system is designed to vary the load (torque) applied to the contracting muscle even though the weight selected remains the same. In theory, the cam is configured to replicate the length-tension relationship and resultant torque curve of the contracting muscle with the greatest amount of resistance applied in the midrange. This system varies the external load imposed on the contracting muscle based on the physical dimensions of the "average" individual. How effectively this design provides truly accommodating resistance throughout the full ROM is debatable.

With each repetition of an exercise, the same muscle group contracts and is resisted concentrically and eccentrically. As with simple weight-pulley systems and free weights, exercises must be performed at relatively slow velocities, thus compromising carryover to many functional activities.

FIGURE 6.48 Variable resistance by means of a cam mechanism in the weight-pulley system is applied to concentric and eccentric contractions of the hamstrings as the knees flex and extend.

Hydraulic and Pneumatic Resistance Devices

Other variable resistance units employ hydraulic or pressurized pneumatic resistance to vary the resistance throughout the ROM. Fluid or air contained in a cylinder is forced through a small opening by a piston. The faster the piston is pushed, the greater the resistance encountered.

These devices allow concentric, reciprocal muscle work to agonist and antagonist muscle groups but no eccentric work. Patients can exercise safely at medium and to some extent fast velocities. These units also allow a patient to accommodate for a painful arc in the ROM.

Advantages and Disadvantages of Variable Resistance Machines

- The obvious advantage of these machines compared to constant load equipment is that the effective resistance is adjusted, at least to some extent, to a muscle's tension-generating capabilities throughout the ROM. The contracting muscle is subjected to near maximal loads at multiple points in the ROM, rather than just one small portion of the range.
- Most pieces of equipment are designed to isolate and exercise specific muscle groups. For example, resisted squats are performed on one machine and hamstring curls on another. Consequently, numerous units are need to exercise all major muscles groups.
- Unlike functional movement, most machines allow only single-plane movements, although some newer units now offer a dual-axis design allowing multiplanar motions that strengthen multiple muscle groups and more closely resemble functional movement patterns.
- The equipment is adjustable to a certain extent to allow individuals of varying heights to perform each exercise in a well-aligned position.
- Each unit provides substantial external stabilization to guide or limit movements. This makes it easier for the patient to learn how to perform the exercise correctly and safely and helps maintain appropriate alignment without assistance or supervision.
- One of the main disadvantages of weight machines is the initial expense and ongoing maintenance costs. Multiple machines, usually 8 to 10 or more, must be purchased to target multiple major muscle groups. Multiple machines also require a large amount of space in a facility.

Elastic Resistance Devices

The use of elastic resistance products in therapeutic exercise programs has become widespread in rehabilitation and has been shown to be an effective method of providing sufficient resistance to improve muscle strength.[146] Resistance training with elastic products also has been shown to be a feasible

alternative to training with weight machines[45] and free weights,[13] generating comparably high levels of muscle activation during exercises.

Despite the popularity of these products, not until the past 10 to 15 years has quantitative information been reported on the actual or relative resistance supplied by elastic products or the level of muscle activation during use.* These studies suggest that the effective use of elastic products for resistance training requires not only the application of biomechanical principles but also an understanding of the physical properties of elastic resistance material.

Types of Elastic Resistance

Elastic resistance products, specifically designed for use during exercise, fall into two broad categories: elastic bands and elastic tubing. Elastic bands and tubing are produced by several manufacturers under different product names, the most familiar of which is Thera-Band® Elastic Resistance Bands and Tubing (Hygenic Corp., Akron, OH). Elastic bands are available in an assortment of grades or thicknesses. Tubing comes in graduated diameters and wall thickness that provide progressive levels of resistance. Color-coding denotes the thickness of the product and grades of resistance.

Properties of Elastic Resistance: Implications for Exercise

A number of studies describing the physical characteristics of elastic resistance have provided quantitative information about its material properties. Knowledge of this information enables a therapist to use elastic resistance more effectively for therapeutic exercise programs.

Effect of elongation of elastic material. Elastic resistance provides a form of variable resistance because the force generated changes as the material is elongated. Specifically, as it is stretched, the amount of resistance (force) produced by an elastic band or tubing increases depending on the *relative change* in the length of the material *(percentage of elongation/deformation)* from the start to the end of elongation. There is a relatively predictable and *linear* relationship between the percentage of elongation and the tensile force of the material.[136,147,152,224,243]

To determine the percentage of elongation, the stretched length must be compared to the resting length of the elastic material. The *resting length* of a band or tubing is its length when it is laid out flat and there is no stretch applied. The actual length of the material before it is stretched has no effect on the force imparted. Rather, it is the percentage of elongation that affects the tensile forces.[224]

The formula for calculating the percentage of elongation/deformation is:[146,243]

Percent of elongation = (stretched length – resting length) ÷ resting length × 100

Using this formula, if a 2-foot length of red tubing, for example, is stretched to 4 feet, the percentage of elongation is 100%. With this in mind, it is understandable why a 1-foot length of the same color tubing stretched to 2 feet (100% elongation) generates the same force as a 2-foot length stretched to 4 feet.[222,223]

Furthermore, the *rate* at which elastic material is stretched does not seem to have a significant effect on the amount of resistance encountered.[224] Consequently, when a patient is performing a particular exercise, so long as the percentage of elongation of the tubing or band is the same from one repetition to the next, the resistance encountered is the same regardless of whether the exercise is performed at slow or fast velocity.

Determination and quantification of resistance. In order to make decisions based on evidence, rather than solely on clinical judgment, about the grade (color) of elastic material to select for a patient's exercise program, a number of studies have been done to quantify the resistance imparted by elastic bands or tubing.[136,147,152,224,243,270] These studies measured and compared the tensile forces generated by various grades of elastic bands or tubing in relation to the percentage of elongation of the material. The forces expected at specific percentages of elongation of each grade of tubing or bands can be calculated by means of linear regression equations. Detailed specifications about the material properties of one brand of elastic resistance products, Thera-Band®, are available at www.thera-bandacademy.com/.

During exercise, the percentage of deformation and resulting resistance (force) from the material is not the only factor that must be considered. The amount of torque (force × distance) imposed by the elastic on the boney lever is also an important consideration. Just because the tension produced by an elastic band or tubing increases as it is stretched, it does not mean that the imposed torque necessarily increases from the beginning to the end of an exercise. In addition to the resistance (force) imposed by the elastic material as it is stretched, the factor of the changing length of the moment arm as the angle of the elastic changes with respect to the moving limb affects the torque imparted by the elastic material.[147] Studies have indicated that bell-shaped torque curves occur, with the peak torque near midrange during exercises with elastic material.[147,223] Careful scrutiny of these studies is necessary to determine if the elastic resistance is at a 90° angle to the moving limb at midrange. As in all forms of dynamic resistance exercise, the length-tension relationship of the contracting muscle also affects its ability to respond to the changing load.

Fatigue characteristics. It has been suggested that elastic resistance products tend to fatigue over time, which causes the material to lose some of its force-generating property.[146] That being said, the extent of *material fatigue* is dependent on the number of times the elastic band or tubing has been stretched (number of stretch cycles) and the percentage of deformation with each stretch.[243]

Studies have shown that the decrease in tensile force is significant but small, with much of the decrease occurring within the first 20[224] or 50[146] stretch cycles. However, in the former study, investigators found that after this small, initial

*135,136,147,152,222,224,243,270

decrease in tensile force occurred, there was no appreciable decrease in the force-generating potential of the tubing after more than 5000 cycles of stretch. In other words, a patient could perform 10 repetitions each of four different exercises, three times a day on a daily basis for 6 weeks with the same piece of tubing before needing to replace it.

Elastic materials also display a property called *viscoelastic creep.* If a constant load is placed on elastic material, in time it becomes brittle and eventually ruptures. Environmental conditions, such as heat and humidity, also affect the force-generating potential of elastic bands and tubing.[146]

Application of Elastic Resistance

Selecting the appropriate grade of material. The thickness (stiffness) of the material affects the level of resistance. A heavier grade of elastic generates greater tension when stretched and, therefore, imparts a greater level of resistance.[136,146,243] As already noted, corresponding levels of resistance have been published for the different grades of bands and tubing.

There is a question of whether similar colors of bands or tubing from different manufacturers may or may not provide similar levels of tension under the same conditions.

FOCUS ON EVIDENCE

In a study[270] comparing similar colors and lengths of Thera-Band® and Cando tubing (Cando Fabrication Enterprises, White Plains, NY), investigators measured (by means of a strain gauge) the forces generated under similar conditions. They found no appreciable differences between the two products except for the thinnest (yellow) and thickest (silver/gray) grades. In those two grades the Cando tubing produced approximately 30% to 35% higher levels of force than the Thera-Band® product. Despite these small differences, investigators suggested that it is prudent to use the same product with the same patient.

Selecting the appropriate length. Elastic bands or tubing come in large rolls and can be cut in varying lengths depending on the specific exercise to be performed and the height of a patient or the length of the extremities. The length of the elastic material should be sufficient to attach it *securely* at both ends. It should be taut but not stretched (*resting length*) at the beginning position of an exercise.

Remember, the percentage of elongation of the material affects the tension produced. Accordingly, it is essential that the same length of elastic resistance is used each time a particular exercise is performed. Otherwise, the imposed load may be too little or too much from one exercise session to the next even though the same grade (thickness) of elastic is used.

Securing bands or tubing. One end is often tied or attached to a fixed object (doorknob, table leg, or D-ring) or secured by having the patient stand on one end of the material. The other end is grasped or fastened to a nylon loop, which is then placed around a limb segment. The material can also be secured to a harness on a patient's trunk for resisted walking activities. The band or tubing can also be held in both hands or looped under both feet for bilateral exercise. Figures 6.49 A, B, and C depict upper or lower extremity and trunk strengthening activities using elastic resistance.

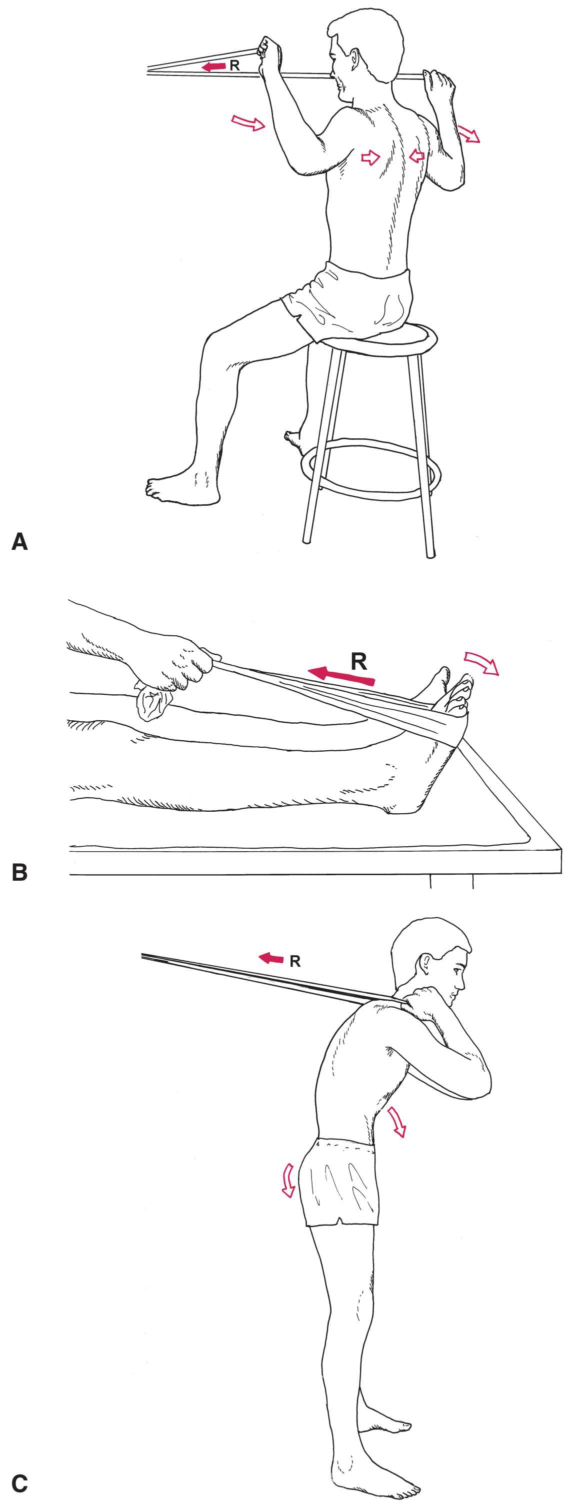

FIGURE 6.49 Use of elastic resistance to strengthen **(A)** upper or **(B)** lower extremity or **(C)** trunk musculature.

Setting up an exercise. With elastic resistance, the muscle receives the maximum resistive force when the material is on a stretch and angled 90° to the lever arm (moving bone). The therapist should determine the limb position at which maximum resistance is desired and anchor the elastic material so it is at a right angle at that portion of the range. When the material is at an acute angle to the moving bone, there is less resistance but greater joint compressive force.

It is important to set up the exercise in the same manner from one exercise session to the next. Each time a patient performs a specific exercise, in addition to using the same length of elastic material the patient should assume the same position. A resource by Page and Ellenbecker[222] described setups for numerous exercises using elastic resistance.

Progressing exercises. Exercises can be progressed by increasing the number of repetitions of an exercise with the same grade of resistance or by using the next higher grade of elastic band or tubing.

Advantages and Disadvantages of Exercise with Elastic Resistance

Advantages

- Elastic resistance products are portable and relatively inexpensive, making them an ideal choice for home exercise programs.
- Because elastic resistance is not significantly gravity-dependent, elastic bands and tubing are extremely *versatile*, allowing exercises to be performed in many combinations of movement patterns in the extremities and trunk and in many positions.[146,147,223]
- It is safe to exercise at moderate to fast velocities with elastic resistance because the patient does not have to overcome the inertia of a rapidly moving weight. As such, it is appropriate for plyometric training (see Chapter 23).

Disadvantages

- One of the most significant drawbacks to the use of elastic resistance is the need to refer to a table of figures for quantitative information about the level of resistance for each color-coded grade of material. This makes it difficult to know which grade to select initially and to what extent changing the grade of the band or tubing changes the level of resistance.
- As with free weights, there is no source of stabilization or control of extraneous movements when an elastic band or tubing is used for resistance. The patient must use muscular stabilization to ensure that the correct movement pattern occurs.
- Although the effects of material fatigue are small with typical clinical use (up to 300% deformation in most exercises), elastic bands and tubing should be replaced on a routine basis to ensure patient safety.[146,243] If many individuals use the same precut lengths of bands or tubing, it may be difficult to determine how much use has occurred.
- Some elastic products contain latex, thus eliminating use by individuals with an allergy to latex. However, there are latex-free products on the market at a relatively comparable cost.

Equipment for Dynamic Stabilization Training

BodyBlade®

The BodyBlade® (Fig. 6.50) is a dynamic, reactive device that produces oscillatory resistance proportional to the force applied when the patient initiates the oscillations with a few quick shakes of the blade.[33,184] While a patient drives the blade, rapidly alternating contractions of agonist and antagonist muscle groups occur in an attempt to control the instability in three planes of motion dictated by movements of the blade. The greater the amplitude or flex of the blade, the greater the resistance. This provides progressive resistance that the patient controls.

FIGURE 6.50 Dynamic stabilization exercises of the upper extremity and trunk using the BodyBlade®. *(Courtesy of BodyBlade/Hymanson, Inc., Los Angeles, CA; 1-800-77BLADE, or 25233;* www.bodyblade.com/.*)*

Initially, the oscillating blade is maintained in various positions in space, particularly those positions in which dynamic stability is required for functional activities. The patient can progress the difficulty of the stabilization exercises by moving the upper extremity through various planes of motion (from sagittal to frontal and ultimately to transverse) as the blade

oscillates. The goal is to develop proximal stability as a foundation of controlled mobility.

FOCUS ON EVIDENCE

Lister and colleagues[184] conducted a study using a repeated measures analysis of surface EMG activity to determine the extent of activation of the stabilizing muscles of the scapula during upper extremity exercise with three forms of resistance (a cuff weight, elastic resistance, and a BodyBlade®). Healthy college athletes ($n = 30$) performed shoulder flexion and abduction with each of the three types of equipment as activity in the upper trapezius, lower trapezius, and serratus anterior muscles was measured. Results of the study demonstrated that significantly greater activity in each of the three scapular stabilizers occurred when shoulder exercises were performed with the blade than with either the cuff weight or elastic resistance. The investigators recommended use of a blade in shoulder rehabilitation to develop scapular stability during arm movements.

Swiss Balls (Stability Balls)

Heavy-duty vinyl balls, usually 20 to 30 inches in diameter, are used for a variety of trunk and extremity stabilization exercises. Use elastic resistance or free weights while on the ball increases the difficulty of exercises. Refer to Chapters 16 and 23 for descriptions of a number of dynamic stabilization exercises using stability balls.

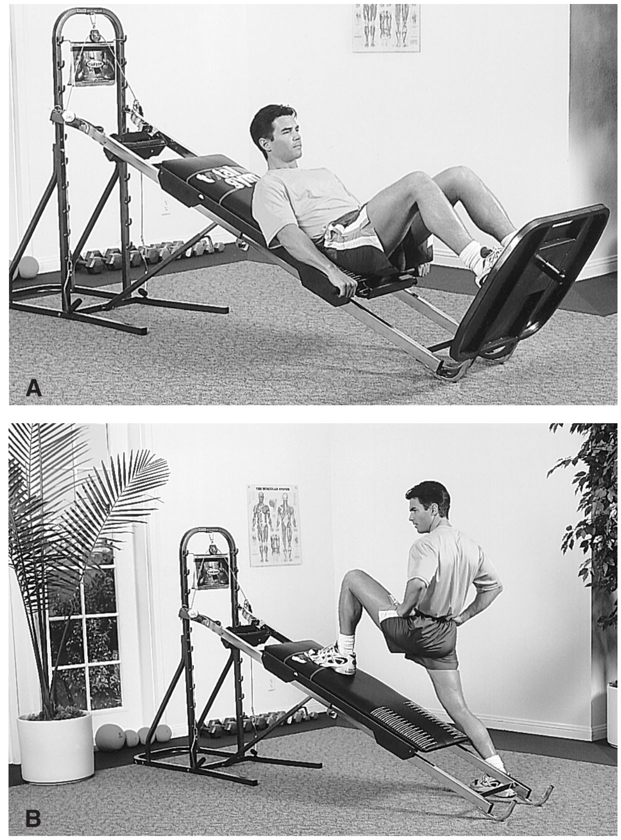

FIGURE 6.51 Closed-chain training: **(A)** in the semi-reclining position and **(B)** standing position using the Total Gym® system. *(Courtesy of Total Gym®, San Diego, CA.)*

Equipment for Closed-Chain Training

Many closed-chain exercises are performed in weight-bearing postures to develop strength, endurance, and stability across multiple joints. Typically, these exercises use partial or full body weight as the source of resistance. Examples in the lower extremities include squats, lunges, and step-ups or step-downs; and in the upper extremities they include push-ups or press-ups in various positions and pull-ups or chin-ups. These exercises are progressed simply by adding resistance with handheld weights, a weighted belt or vest, or elastic resistance. Progressing from bilateral to unilateral weight bearing (when feasible) also increases the exercise load. The following equipment is designed specifically for closed-chain training and has features to improve muscle performance across multiple joints.

Body Weight Resistance: Multipurpose Exercise Systems

The Total Gym® system, for example, uses a glide board, which can be set at 10 incline angles, enabling a patient to perform bilateral or unilateral closed-chain strengthening and endurance exercises in positions that range from partially reclining to standing (Fig. 6.51 A&B). The level of resistance on the Total Gym apparatus is increased or decreased by adjusting the angle of the glide board on the incline.

Performance of bilateral and, later, unilateral squatting exercises in a semi-reclining position allows the patient to begin closed-chain training in a partially unloaded (partial weight-bearing) position early in the rehabilitation program. Later, the patient can progress to forward lunges (where the foot slides forward on the glide board) while in a standing position.

CLINICAL TIP

The Total Gym® system also can be set up for trunk exercises and open-chain exercises for the upper or lower extremities.

Slide Boards

The ProFitter® (Fig. 6.52) consists of a moving platform that slides side to side across an elliptical surface against adjustable resistance. Although it is most often used with the patient standing for lower extremity rehabilitation, it can also provide upper extremity closed-chain resisted movements and trunk stability. Medial-lateral or anterior-posterior movements are possible.

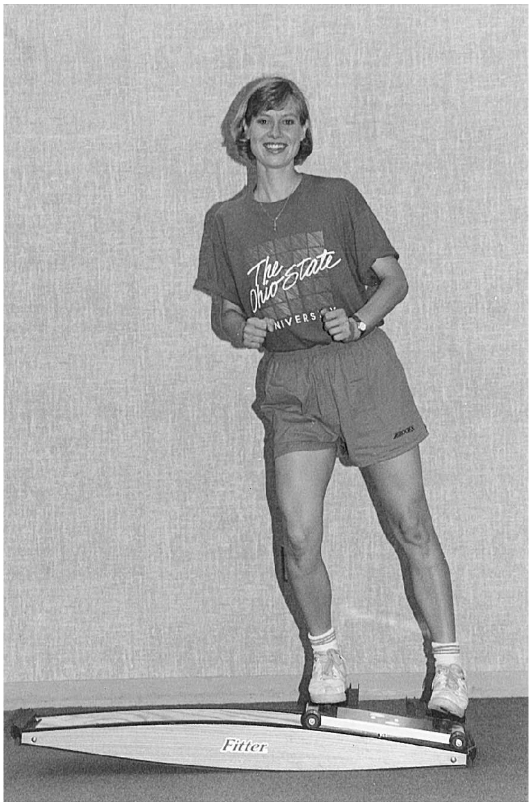

FIGURE 6.52 Pro Fitter provides closed-chain resistance to lower extremity musculature in preparation for functional activities.

Balance Equipment

A balance board (wobble board) or BOSU® (in the shape of a half sphere with a flat and round side) are used primarily for stabilization, proprioceptive, and perturbation training. Bilateral or unilateral weight bearing through the upper or lower extremity can be performed on this equipment to develop strength and stability. Some balance boards, such as the BAPS (Biomechanical Ankle Platform System) board, have interchangeable half spheres in several sizes that are placed under the platform to progressively increase the difficulty of the balance activity. Refer to Chapters 8 and 23 for examples of balance activities using various types of equipment.

Mini-Trampolines (Rebounders)

Mini-trampolines enable the patient to begin gentle, bilateral or unilateral bouncing activities on a resilient surface to decrease the impact on joints. A patient can jog, jump, or hop in place. "Mini-tramps" that have a waist-height bar (attached to the frame) to hold onto provide additional safety.

Reciprocal Exercise Equipment

Similar to other types of equipment that can be used for closed-chain training, reciprocal exercise devices strengthen multiple muscle groups across multiple joints. They also are appropriate for low-intensity, high-repetition resistance training to increase muscular endurance and reciprocal coordination of the upper or lower extremities and improve cardiopulmonary fitness. They often are used for warm-up or cool-down exercises prior to and after more intense resistance training. Resistance is imparted by an adjustable friction device or by hydraulic or pneumatic resistance.

Stationary Exercise Cycles

The stationary exercise cycle (upright or recumbent) is used to increase lower extremity strength and endurance. An upright cycle requires greater trunk control and balance than a recumbent cycle. A few exercise cycles provide resistance to the upper extremities as well. Resistance can be graded to challenge the patient progressively. Distance, speed, or duration of exercise can be monitored.

The exercise cycle provides resistance to muscles during repetitive, nonimpact, and reciprocal movements of the extremities. Passive devices resist only concentric muscle activity as the patient performs pushing or pulling movements. Motor-driven exercise cycles can be adjusted to provide eccentric as well as concentric resistance. Adjusting the placement of the seat alters the arc of motion that occurs in the lower extremities.

Portable Resistive Reciprocal Exercise Units

A number of portable resistive exercisers are effective alternatives to an exercise cycle for repetitive, reciprocal exercise. One such product, the Chattanooga Group Exerciser® (Fig. 6.53), can be used for lower extremity exercise by placing the unit on the floor in front of a chair or wheelchair. This is particularly appropriate for a patient who is unable to get on and off an exercise cycle. In addition, it can be placed on a table for upper extremity exercise. Resistance can be adjusted to meet the abilities of individual patients.

FIGURE 6.53 Resisted reciprocal exercise using the Chattanooga Exerciser.® *(Courtesy of Chattanooga Group, Inc., Hixon, TN.)*

Stair-Stepping Machines

The StairMaster® (Fig. 6.54) and the Climb Max 2000® are examples of stepping machines that allow the patient to perform reciprocal pushing movements against adjustable resistance to make the weight-bearing activity more difficult. Stepping machines provide nonimpact, closed-chain strengthening as an alternative to walking or jogging on a treadmill. A patient can also kneel next to the unit and place both hands on the foot plates to use this equipment for upper extremity closed-chain exercises.

FIGURE 6.54 A stepping machine provides resistance during alternating lower extremity-pushing movements that simulate stair-climbing.

Elliptical Trainers and Cross-Country Ski Machines

Elliptical trainers and cross-country ski machines also provide nonimpact, reciprocal resistance to the lower extremities in an upright, weight-bearing position. Variable incline adjustments of these units further supplement resistance options. Both types of equipment also incorporate sources of reciprocal resistance to the upper extremities into their designs.

Upper Extremity Ergometers

Upper extremity ergometers provide resistance primarily to the upper body to increase strength and muscular enduranc (Fig. 6.55). Forward and reverse cycling at varying speeds is possible. As with stationary cycles, upper extremity ergometers also are used to improve cardiopulmonary fitness. Typically, the patient is seated, but some ergometers can be used in a standing position to lessen the extent of elevation of the arms necessary with each revolution. This is particularly helpful for patients with impingement syndromes of the shoulder.

FIGURE 6.55 An upper extremity ergometer is used for upper body strength and endurance training and cardiopulmonary fitness.

Isokinetic Testing and Training Equipment

Isokinetic dynamometers (rate-limiting devices that control the velocity of motion) provide accommodating resistance during dynamic exercises of the extremities or trunk (see Fig 6.9). The equipment supplies resistance proportional to the force generated by the person using the machine. The preset rate of movement (degrees per second) cannot be exceeded no matter how vigorously the person pushes against the force arm. Therefore, the muscle contracts to its fullest capacity at all points in the ROM.

Features of Isokinetic Dynamometers

Features include computerized testing capabilities; passive and active modes that permit open-chain, concentric and eccentric testing and training; and velocity settings from 0°/sec for isometric exercise, up to 500°/sec for the concentric mode, and up to 120° to 250°/sec for the eccentric mode. Computer programming allows limb movement within a specified range. Single-joint, uniplanar, open-chain movements are most common, but adaptations are available that permit a limited number of multiplanar movement patterns and multijoint, closed-chain exercises. Reciprocal training of agonist and antagonist and concentric/eccentric training of the same muscle group are possible.

Advantages and Disadvantages of Isokinetic Equipment

The characteristics of isokinetic exercise and equipment have already been presented in an earlier section of this chapter. The advantages and disadvantages of isokinetic dynamometers include the following.

Advantages

- If the patient puts forth a maximum effort, isokinetic equipment provides maximum resistance at all points in the ROM as a muscle contracts.
- Both high- and low-velocity training can be done safely and effectively.
- The equipment accommodates for a painful arc of motion.
- As a patient fatigues, exercise can still continue.
- Isolated strengthening of muscle groups is possible to correct strength deficits in specific muscle groups.
- External stabilization keeps the patient and moving segment well aligned.
- Concentric and eccentric contractions of the same muscle group can be performed repeatedly, or reciprocal exercise of opposite muscle groups can be performed, allowing one muscle group to rest while its antagonist contracts; the latter method minimizes muscle ischemia.
- Computer-based visual or auditory cues provide feedback to the patient so submaximal to maximal work can be carried out more consistently.

Disadvantages

- The equipment is large and expensive to purchase and maintain.
- Setup time and assistance from personnel are necessary if a patient is to exercise multiple muscle groups.
- Most units allow only open-chain (nonweight-bearing) movement patterns, which do not simulate most lower extremity functions and some upper extremity functions.
- Although functional movements typically occur in combined patterns and at varying velocities, most exercises are performed in a single plane and at a constant velocity.
- Although the range of concentric training velocities (up to 500°/sec) is comparable to some lower extremity limb speeds during functional activities, even the upper limits of this range of velocities cannot begin to approximate the rapid limb speeds that are necessary during many sports-related motions, such as throwing. In addition, the eccentric velocities available, at best, only begin to approach medium-range speeds, far slower than the velocity of movement associated with quick changes of direction and deceleration. Both of these limitations in the range of training velocities compromise carryover to functional goals.

Independent Learning Activities

Critical Thinking and Discussion

1. What physical findings from an examination and evaluation of a patient would lead you to determine that resistance exercises were an appropriate intervention?
2. What are the benefits and limitations of isometric, dynamic (constant or variable resistance), and isokinetic exercises?
3. What are the key changes that occur in muscle strength and endurance throughout the life span?
4. You have been asked to design a resistance exercise program as part of a total fitness program for a group of 7 to 9-year-old soccer players (boys and girls).
   a. Indicate the exercises you would include, the equipment you need, and the guidelines for intensity, volume, frequency, and rest.
   b. What special precautions during resistance training should be taken with children and why?
5. Analyze five daily living tasks or recreational activities that you currently perform or would like to be able to perform effectively and efficiently. Identify what aspects of muscle performance (strength, power, endurance) and other parameters of function, such as mobility (flexibility), stability, balance, and coordinated movement, are involved in each of these tasks.
6. Develop an in-service instructional presentation that deals with the appropriate and effective use of elastic resistance products.
7. You have been asked to help design a circuit weight training sequence at a soon-to-open fitness facility at the outpatient treatment center where you work. Select equipment to meet the needs of beginning and advanced individuals. Establish general guidelines for intensity, repetitions and sets, order of exercise, rest intervals, and frequency.
8. Design a resistance-training program as part of a total fitness program for a group of older adults who participate in activities at a community-based senior citizen center. All participants are ambulatory and range in age from 65 to 85 years. Each has received clearance from his or her physician to participate in the program. What types of resistance equipment and levels of resistance would you recommend? Identify special precautions you would want to take.

Laboratory Practice

1. Perform manual resistance exercise to all muscle groups of the upper and lower extremities in the following positions: supine, prone, side-lying, and sitting. What are the major

limitations to effective, full-range strengthening in each of these positions?

2. Apply manual resistance exercises to each of the muscles of the wrist, fingers, and thumb.
3. Practice upper extremity and lower extremity D_1 and D_2 PNF exercises on your laboratory partner's right *and* left extremities.
4. Determine a 1-RM and 10-RM for the following muscle groups: shoulder flexors, shoulder abductors, shoulder external rotators, elbow flexors and extensors, hip abductors, hip flexors, knee flexors and extensors. Select one upper and one lower extremity muscle group. Determine a 1-RM or 10-RM with free weights in two positions. Determine where in the ROM maximum resistance is encountered. Then determine a 1-RM or 10-RM with a pulley system. Compare your results.
5. Set up and safely apply exercises with elastic bands or tubing to strengthen the major muscle groups of the upper and lower extremities. Include a dynamic open-chain, a dynamic closed-chain, and an isometric exercise for each muscle group.
6. Demonstrate a series of simulated functional activities that could be used in the final stages of rehabilitation to continue to improve muscle performance as a transition into independent functional activities for a mail carrier, a nurse's aide who works in a skilled nursing facility, a ski instructor, a baseball player, and a daycare worker who cares for a group of active toddlers (each weighing approximately 25 pounds).

CHAPTER

7

Principles of Aerobic Exercise

KAREN HOLTGREFE, PT, DHS, OCS

There are numerous sources from which to obtain information on training for endurance in athletes and healthy young people and for individuals with coronary heart disease. Information or emphasis on endurance training and the improvement of fitness in the individual who has other types of chronic disease or disability is beginning to emerge. Using the most recent research, the American College of Sports Medicine (ACSM) published basic guidelines for several of the more common chronic conditions.[1-3] This chapter uses information from well-known sources to demonstrate that the physical therapist can use aerobic-type activity when working with either healthy individuals or patients with a variety of conditions. In addition, some fundamental information about cardiovascular and respiratory parameters in children and the elderly, as well as the young or middle-aged adult, is presented so the physical therapist can be prepared to treat individuals of all ages.

Key Terms and Concepts

Physical Activity

Physical activity as defined by ACSM[1] and the Centers for Disease Control and Prevention (CDC)[4] is "any bodily movement produced by the contraction of skeletal muscles that result in a substantial increase over resting energy expenditure."

Exercise

Planned and structured physical activity designed to improve or maintain physical fitness.

Physical Fitness

Fitness is a general term used to describe the ability to perform physical work. Performing physical work requires cardiorespiratory functioning, muscular strength and endurance, and musculoskeletal flexibility. Optimum body composition is also included when describing fitness.

To become physically fit, individuals must participate regularly in some form of physical activity that uses large muscle groups and challenges the cardiorespiratory system. Individuals of all ages can improve their general fitness status by participating in activities that include walking, biking, running, swimming, stair climbing, cross-country skiing, and/or training with weights.

Fitness levels can be described on a continuum from poor to superior based on energy expenditure during a bout of physical work.[11,12] These ratings are often based on direct or indirect measurement of the body's maximum oxygen consumption ($VO_{2\ max}$). Oxygen consumption is influenced by age, gender, heredity, inactivity, and disease.

Maximum Oxygen Consumption

Maximum oxygen consumption ($VO_{2\ max}$) is a measure of the body's capacity to use oxygen.[1,11,12] It is usually measured when performing an exercise that uses many large muscle groups such as swimming, walking, and running. It is the maximum amount of oxygen consumed per minute when the individual has reached maximum effort. It is usually expressed relative to body weight, as milliliters of oxygen per kilogram of body weight per minute (mL/kg per minute). It is dependent on the transport of oxygen, the oxygen-binding capacity of the blood, cardiac function, oxygen extraction capabilities, and muscular oxidative potential.

Endurance

Endurance (a measure of fitness) is the ability to work for prolonged periods of time and the ability to resist fatigue.[11,12] It includes muscular endurance and cardiovascular endurance. Muscular endurance refers to the ability of an isolated muscle group to perform repeated contractions over a period of time, whereas cardiovascular endurance refers to the ability to perform large muscle dynamic exercise, such as walking, swimming, and/or biking for long periods of time.

Aerobic Exercise Training (Conditioning)

Aerobic exercise training, or conditioning, is augmentation of the energy utilization of the muscle by means of an exercise program.[11,12] The improvement of the muscle's ability to use energy is a direct result of increased levels of oxidative enzymes in the muscles, increased mitochondrial density and size, and an increased muscle fiber capillary supply.

- Training is dependent on exercise of sufficient frequency, intensity, and time.
- Training produces cardiovascular and/or muscular adaptation and is reflected in an individual's endurance.
- Training for a particular sport or event is dependent on the *specificity principle*[11,12]—that is, the individual improves in the exercise task used for training and may not improve in other tasks. For example, swimming may enhance one's performance in swimming events but may not improve one's performance in treadmill running.

Adaptation

The cardiovascular system and the muscles used *adapt* to the training stimulus over time.[11,12] Significant changes can be measured in as little as 10 to 12 weeks.

Adaptation results in increased efficiency of the cardiovascular system and the active muscles. Adaptation represents a variety of neurological, physical, and biochemical changes in the cardiovascular and muscular systems. Performance improves in that the same amount of work can be performed after training but at a lower physiological cost.

Adaptation is dependent on the ability of the organism to change and the training stimulus threshold (the stimulus that elicits a training response). The person with a low level of fitness has more potential to improve than the one who has a high level of fitness.

Training stimulus thresholds are variable. The higher the initial level of fitness, the greater the intensity of exercise needed to elicit a significant change.

Myocardial Oxygen Consumption

Myocardial oxygen consumption is a measure of the oxygen consumed by the myocardial muscle.[1,3,11,12] The need or demand for oxygen is determined by the heart rate (HR), systemic blood pressure, myocardial contractility, and afterload. Afterload is determined by the left ventricular wall tension and central aortic pressure. It is the ventricular force required to open the aortic valve at the beginning of systole. Left ventricular wall tension is primarily determined by ventricular size and wall thickness.

The ability to supply the myocardium with oxygen is dependent on the arterial oxygen content (blood substrate), hemoglobin oxygen dissociation, and coronary blood flow, which is determined by aortic diastolic pressure, duration of diastole, coronary artery resistance, and collateral circulation. In a healthy individual, a balance between myocardial oxygen supply and demand is maintained during maximum exercise. When the demand for oxygen is greater than the supply, myocardial ischemia results.

Because the myocardial muscle extracts 70% to 75% of the oxygen from the blood during rest, its main source of supply

during exercise is through an increase in coronary blood flow. The clinical relevance is described in Box 7.1.

BOX 7.1 Clinical Relevance—Exertional Angina

Persons who have coronary occlusion may not present with any type of chest pain/symptoms (angina) until they need to exert themselves. This is because when the body works harder the heart rate increases, diastolic filling time decreases, and increased coronary blood flow is sacrificed by the reduced time for filling the coronary arteries. Without an adequate blood supply, the underlying cardiac tissue no longer receives the oxygen needed for metabolic activity, resulting in anginal pain/symptoms.

Deconditioning

Deconditioning occurs with prolonged bed rest, and its effects are frequently seen in the patient who has had an extended, acute illness or long-term chronic condition. Decreases in maximum oxygen consumption, cardiac output (stroke volume), and muscular strength occur rapidly. These effects are also seen, although possibly to a lesser degree, in the individual who has spent a period of time on bed rest without any accompanying disease process and in the individual who is sedentary because of lifestyle and increasing age. Deconditioning effects associated with bed rest are summarized in Box 7.2.

BOX 7.2 Deconditioning Effects Associated with Bed Rest[3]

↓ Muscle mass
↓ Strength
↓ Cardiovascular function
↓ Total blood volume
↓ Plasma volume
↓ Heart volume
↓ Orthostatic tolerance
↓ Exercise tolerance
↓ Bone mineral density

Energy Systems, Energy Expenditure, and Efficiency

Energy Systems

Energy systems are metabolic systems involving a series of biochemical reactions resulting in the formation of adenosine triphosphate (ATP), carbon dioxide, and water.[11,12] The cell uses the energy produced from the conversion of ATP to adenosine diphosphate (ADP) and phosphate (P) to perform metabolic activities. Muscle cells use this energy for actin-myosin cross-bridge formation when contracting. There are three major energy systems. The intensity and duration of activity determine when and to what extent each metabolic system contributes.

Phosphagen, or ATP-PC, System

The ATP-PC system (adenosine triphosphate-phosphocreatine) has the following characteristics.

- Phosphocreatine and ATP are stored in the muscle cell.
- Phosphocreatine is the chemical fuel source.
- No oxygen is required (anaerobic).
- When muscle is rested, the supply of ATP-PC is replenished.
- The maximum capacity of the system is small (0.7 mol ATP).
- The maximum power of the system is great (3.7 mol ATP/min).
- The system provides energy for short, quick bursts of activity.
- It is the major source of energy during the first 30 seconds of intense exercise.

Anaerobic Glycolytic System

The anaerobic glycolytic system has the following characteristics.

- Glycogen (glucose) is the fuel source (glycolysis).
- No oxygen is required (anaerobic).
- ATP is resynthesized in the muscle cell.
- Lactic acid is produced (by-product of anaerobic glycolysis).
- The maximum capacity of the system is intermediate (1.2 mol ATP).
- The maximum power of the system is intermediate (1.6 mol ATP/min).
- The systems provide energy for activity of moderate intensity and short-duration.
- It is the major source of energy from the 30th to 90th second of exercise.

Aerobic System

The aerobic system has the following characteristics.

- Glycogen, fats, and proteins are fuel sources and are utilized relative to their availability and the intensity of the exercise.
- Oxygen is required (aerobic).
- ATP is resynthesized in the mitochondria of the muscle cell. The ability to metabolize oxygen and other substrates is related to the number and concentration of the mitochondria and cells.
- The maximum capacity of the system is great (90.0 mol ATP).
- The maximum power of the system is small (1.0 mol ATP/min).
- The system predominates over the other energy systems after the second minute of exercise.

Recruitment of Motor Units

Recruitment of motor units is dependent on the rate of work. Fibers are recruited selectively during exercise.[11,12]

- *Slow-twitch fibers (type I)* are characterized by a slow contractile response, are rich in myoglobin and mitochondria, have a high oxidative capacity and a low anaerobic capacity, and are recruited for activities demanding endurance. These fibers are supplied by small neurons with a low threshold of activation and are used preferentially in low-intensity exercise.
- *Fast-twitch fibers (type IIB)* are characterized by a fast contractile response, have a low myoglobin content and few mitochondria, have a high glycolytic capacity, and are recruited for activities requiring power.
- *Fast-twitch fibers (type IIA)* have characteristics of both type I and type IIB fibers and are recruited for both anaerobic and aerobic activities.

Functional Implications

- *Bursts of intense activity* lasting only seconds develop muscle strength and stronger tendons and ligaments. ATP is supplied by the phosphagen system.
- *Intense activity* lasting 1 to 2 minutes repeated after 4 minutes of rest or mild exercise enhances anaerobic power. ATP is supplied by the phosphagen and anaerobic glycolytic system.
- Activity with *large muscles*, which is less than maximum intensity for 3 to 5 minutes repeated after rest or mild exercise of similar duration, may develop aerobic power and endurance capabilities. ATP is supplied by the phosphagen, anaerobic glycolytic, and aerobic systems.
- Activity of *submaximum intensity* lasting 20 to 30 minutes or more taxes a high percentage of the aerobic system and develops endurance.

Energy Expenditure

Energy is expended by individuals engaging in physical activity and is often expressed in kilocalories. Activities can be categorized as light, moderate, or heavy by determining the energy cost. The energy cost of any activity is affected by mechanical efficiency and body mass. Factors that affect both walking and running are terrain, stride length, and air resistance.[11,12]

Quantification of Energy Expenditure

Energy expended is computed from the amount of oxygen consumed. Units used to quantify energy expenditure are kilocalories and METs.

- A *kilocalorie* is a measure expressing the energy value of food. It is the amount of heat necessary to raise 1 kilogram (kg) of water 1°C. A kilocalorie (kcal) can be expressed in oxygen equivalents. Five kilocalories equal approximately 1 liter of oxygen consumed (5 kcal = 1 liter O_2).[1,11,12]
- A *MET* is defined as the oxygen consumed (milliliters) per kilogram of body weight per minute (mL/kg). It is equal to approximately 3.5 mL/kg per minute.[1,11,12]

Classification of Activities

Activities are classified as light, moderate, or heavy according to the energy expended or the oxygen consumed while accomplishing them.[11,12]

Light work for the average male (65 kg) requires 2.0 to 4.9 kcal/min, or 6.1 to 15.2 mL O_2/kg per minute, or 1.6 to 3.9 METs. Strolling 1.6 km/hr, or 1.0 mph, is considered light work.

Heavy work for the average male (65 kg) requires 7.5 to 9.9 kcal/min, or 23.0 to 30.6 mL O_2/kg per minute, or 6.0 to 7.9 METs. Jogging 8.0 km/hr, or 5.0 mph, requires 25 to 28 mL O_2/kg per minute and is considered heavy work. The energy expended is equivalent to 8 to 10 kcal/min, or 7 to 8 METs.

The energy expenditure necessary for most industrial jobs requires more than three times the energy expenditure at rest. Energy expenditure of certain physical activities can vary, depending on factors such as skill, pace, and fitness level (Box 7.3).

BOX 7.3 Daily Energy Expenditure

The average individual engaged in normal daily tasks expends 1800 to 3000 kcal per day. Athletes engaged in intense training can use more than 10,000 kcal per day.

Data from Wilmore, JH, and Costill, DL: *Physiology of Sport and Exercise.* Champaign, IL: Human Kinetics, 1994.

Efficiency

Efficiency is usually expressed as a percentage[11,12] (Box 7.4).

Work output equals force times distance ($W = F \times D$). It can be expressed in power units or work per unit of time ($P = w/t$). On a treadmill, work equals the weight of the subject times the vertical distance the subject is raised walking up the incline of the treadmill. On a bicycle ergometer, work equals the distance (which is the circumference of the flywheel times the number of revolutions) times the bicycle resistance.

Work input equals energy expenditure and is expressed as the net oxygen consumption per unit of time. With aerobic exercise, the resting volume of oxygen used per unit of time (VO_2 value) is subtracted from the oxygen consumed during 1 minute of the steady-state period.

- Steady state is reached within 3 to 4 minutes after exercise has started if the load or resistance is kept constant.
- In the steady-state period, VO_2 remains at a constant (steady) value.

BOX 7.4 Efficiency Expressed as a Percentage

Percent efficiency = useful work output/energy expended or work input × 100

Total net oxygen cost is multiplied by the total time in minutes the exercise is performed. The higher the net oxygen cost, the lower the efficiency in performing the activity. Efficiency of large muscle activities is usually 20% to 25%.

Physiological Response to Aerobic Exercise

The rapid increase in energy requirements during exercise requires equally rapid circulatory adjustments to meet the increased need for oxygen and nutrients to remove the end-products of metabolism, such as carbon dioxide and lactic acid, and to dissipate excess heat. The shift in body metabolism occurs through a coordinated activity of all the systems of the body: neuromuscular, respiratory, cardiovascular, metabolic, and hormonal (Box 7.5). Oxygen transport and its utilization by the mitochondria of the contracting muscle are dependent on adequate blood flow in conjunction with cellular respiration.[11,12]

Cardiovascular Response to Exercise

Exercise Pressor Response

Stimulation of small myelinated and unmyelinated fibers in skeletal muscle involves a sympathetic nervous system (SNS) response. The central pathways are not known.[1,3, 11,12]

- The SNS response includes generalized peripheral vasoconstriction in nonexercising muscles and increased myocardial contractility, an increased heart rate, and an increased systolic blood pressure. This results in a marked increase and redistribution of the cardiac output.
- The degree of the response equals the muscle mass involved and the intensity of the exercise.

Cardiac Effects

- The frequency of sinoatrial node depolarization increases, as does the heart rate.
- There is a decrease in vagal stimuli as well as an increase in SNS stimulation.
- There is an increase in the force development of the cardiac myofibers. A direct inotropic response of the SNS increases myocardial contractility.

BOX 7.5 Factors Affecting the Response to Acute Exercise

Ambient temperature, humidity, and altitude can affect the physiological responses to acute exercise. Diurnal fluctuations as well as changes associated with a female subject's menstrual cycle can affect these responses as well. Therefore, researchers control these factors as much as possible when evaluating the response to exercise.

Peripheral Effects

Net reduction in total peripheral resistance. Generalized vasoconstriction occurs that allows blood to be shunted from the nonworking muscles, kidneys, liver, spleen, and splanchnic area to the working muscles. A locally mediated reduction in resistance in the working muscle arterial vascular bed, independent of the autonomic nervous system, is produced by metabolites such as Mg^{2+}, Ca^{2+}, ADP, and P_{CO_2}. The veins of the working and nonworking muscles remain constricted.

Increased cardiac output. The cardiac output increases because of the increase in myocardial contractility, with a resultant increase in stroke volume, heart rate, blood flow through the working muscle, and an increase in the constriction of the capacitance vessels on the venous side of the circulation in both the working and nonworking muscles, raising the peripheral venous pressure.

Increase in systolic blood pressure. The increase in systolic blood pressure is the result of the augmented cardiac output.

Respiratory Response to Exercise

- Respiratory changes occur rapidly, even before the initiation of exercise.[11,12] Gas exchange (O_2, CO_2) increases across the alveolar-capillary membrane by the first or second breath. Increased muscle metabolism during exercise results in more O_2 extracted from arterial blood, resulting in an increase in venous P_{CO_2} and H^+, an increase in body temperature, increased epinephrine, and increased stimulation of receptors of the joints and muscles. Any of these factors alone or in combination may stimulate the respiratory system. Baroreceptor reflexes, protective reflexes, pain, emotion, and voluntary control of respiration may also contribute to the increase in respiration.
- Minute ventilation increases as respiratory frequency and tidal volume increase.
- Alveolar ventilation, occurring with the diffusion of gases across the capillary-alveolar membrane, increases 10- to 20-fold during heavy exercise to supply the additional oxygen needed and excrete the excess CO_2 produced.

Responses Providing Additional Oxygen to Muscle

Increased Blood Flow

The increased blood flow to the working muscle previously discussed provides additional oxygen.

Increased Oxygen Extraction

There is also extraction of more oxygen from each liter of blood. There are several changes that allow for this.

- A decrease of the local tissue P_{O_2} occurs because of the use of more oxygen by the working muscle. As the partial pressure of oxygen decreases, the unloading of oxygen from hemoglobin is facilitated.

- The production of more CO_2 causes the tissue to become acidotic (the hydrogen ion concentration increases) and the temperature of the tissue to increase. Both situations increase the amount of oxygen released from hemoglobin at any given partial pressure.
- The increase of red blood cell 2,3-diphosphoglycerate (DPG) produced by glycolysis during exercise also contributes to the enhanced release of oxygen.

Oxygen Consumption

Factors determining how much of the oxygen is consumed are:

- Vascularity of the muscles.
- Fiber distribution.
- Number of mitochondria.
- Oxidative mitochondrial enzymes present in the fibers. The oxidative capacity of the muscle is reflected in the arteriovenous oxygen difference (a-vO_2 difference), which is the difference between the oxygen content of arterial and venous blood.

Testing as a Basis for Exercise Programs

Testing for physical fitness of healthy individuals should be distinct from graded exercise testing of convalescing patients, individuals with symptoms of coronary heart disease, or individuals who are 35 years or older but asymptomatic.[1-3] Regardless of the type of testing, the level of performance is based on the submaximum or maximum oxygen uptake ($VO_{2\ max}$) or the symptom-limited oxygen uptake. The capacity of the individual to transport and utilize oxygen is reflected in the oxygen uptake. Readers are referred to publications by the ACSM[1-3] for additional information.

Fitness Testing of Healthy Subjects

Field tests for determining cardiovascular fitness include the time to run 1.5 miles or the distance run in 12 minutes. These measures correlate well with $VO_{2\ max}$, but their use is limited to young persons or middle-aged individuals who have been carefully screened and have been jogging or running for some time.[1,3] Other field tests include the 1-mile walk test, 6-minute walk test, and step tests. These tests are more suitable for individuals who are not as physically active.

Multistage testing can provide a direct measurement of $VO_{2\ max}$ by analyzing samples of expired air.[1,3] Testing is usually completed in four to six treadmill stages, which progressively increase in speed and or grade. Each stage is 3 to 6 minutes long. Electrocardiographic (ECG) monitoring is performed during the testing. Maximum oxygen uptake can be determined when the oxygen utilization plateaus despite an increase in workload.

Stress Testing for Convalescing Individuals and Individuals at Risk

Individuals undergoing stress testing should have a physical examination, be monitored by the ECG, and be closely observed at rest, during exercise, and during recovery (Fig. 7.1).

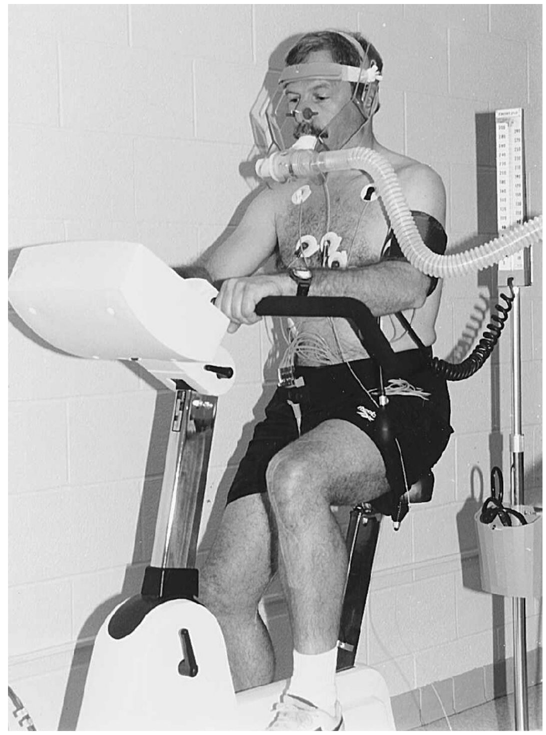

FIGURE 7.1 Cycle ergometer stress test with electrocardiogram monitoring.

Principles of Stress Testing

The principles of stress testing include the following.[1,3]

- Changing the workload by increasing the speed and/or grade of the treadmill or the resistance on the bicycle ergometer
- An initial workload that is low in terms of the individual's anticipated aerobic threshold
- Maintaining each workload for 1 minute or longer
- Terminating the test at the onset of symptoms or a definable abnormality of the ECG
- When available, measuring the individual's maximum oxygen consumption

Purpose of Stress Testing

In addition to serving as a basis for determining exercise levels or the exercise prescription, the stress test:

- Helps establish a diagnosis of overt or latent heart disease.
- Evaluates cardiovascular functional capacity as a means of clearing individuals for strenuous work or exercise programs.

- Determines the physical work capacity in kilogram-meters per minute (kg-m/min) or the functional capacity in METs.
- Evaluates responses to exercise training and/or preventive programs.
- Assists in the selection and evaluation of appropriate modes of treatment for heart disease.
- Increases individual motivation for entering and adhering to exercise programs.
- Is used clinically to evaluate patients with chest sensations or a history of chest pain to establish the probability that such patients have coronary disease. It can also evaluate the functional capacity of patients with chronic disease.

Preparation for Stress Testing

All individuals who are taking a stress test should:

- Have had a physical examination.
- Be monitored by ECG and closely observed at rest, during exercise, and during recovery.
- Sign a consent form.

PRECAUTIONS: Precautions to be taken are summarized in Box 7.6. They are applicable for both stress testing and the exercise program.[1,3]

Termination of Stress Testing

Endpoints requiring termination of the test period are[1]:

- Progressive angina.
- A significant drop in systolic pressure in response to an increasing workload.
- Lightheadedness, confusion, pallor, cyanosis, nausea, or peripheral circulatory insufficiency.
- Abnormal ECG responses including ST segment depression greater than 4 mm.
- Excessive rise in blood pressure.
- Subject wishes to stop.

BOX 7.6 Precautions for Stress Testing and Exercise Program

Cardiopulmonary changes occur with stress testing and exercises. Monitor and recognize the following.

- Monitor the pulse to assess abnormal increases in heart rate.
- Blood pressure increases with exercise approximately 7 to 10 millimeters (mm) of mercury (Hg) per MET of physical activity.
  - Systolic pressure should not exceed 220 to 240 mm Hg.
  - Diastolic pressure should not exceed 120 mm Hg.
- Rate and depth of respiration increase with exercise.
  - Respiration should not be labored.
  - The individual should have no perception of shortness of breath.
- The increase in blood flow while exercising, which regulates core temperature and meets the demands of the working muscles, results in changes in the skin of the cheeks, nose, and earlobes. They become pink, moist, and warm to the touch.

Multistage Testing

Each of the four to six stages lasts approximately 1 to 6 minutes. Differences in protocols involve the number of stages, magnitude of the exercise (intensity), equipment used (bicycle, treadmill), duration of stages, endpoints, position of body, muscle groups exercised, and types of effort (Box 7.7).[1,3]

Protocols have been developed for multistage testing. The most popular treadmill protocol is the Bruce protocol. Treadmill speed and grade are changed every 3 minutes. Speed increases from 1.7 mph up to 5.0 mph, and the initial grade of 10% increases up to 18% during the five stages.

Determinants of an Exercise Program

Just as testing for fitness should be distinct from stress testing for patients or individuals at high risk, training programs for healthy individuals are distinct from the exercise prescription for individuals with cardiopulmonary disease.

Effective endurance training for any population must produce a conditioning or cardiovascular response. Elicitation of the cardiovascular response is dependent on several critical elements of exercise. A recommendation by ACSM[1] and others[11,12] is to use the FITT method: *F*requency, *I*ntensity, *T*ime (duration), and *T*ype of exercise.[1]

Frequency

There is no clear-cut information provided on the most effective frequency of exercise for adaptation to occur. Frequency may be a less important factor than intensity or duration in exercise training. Frequency varies, dependent on the health and age of the individual. Optimal frequency of training is generally three to four times a week. If training is at a low-intensity, greater frequency may be beneficial. A frequency of two times a week does not generally evoke cardiovascular changes, although older individuals and convalescing patients may benefit from a program of that frequency.

Intensity

Determination of the appropriate intensity of exercise to use is based on the overload principle and the specificity principle.[1,3,11,12]

Overload Principle

Overload is stress on an organism that is greater than that regularly encountered during everyday life. To improve cardiovascular and muscular endurance, an overload must be applied to these systems. The exercise load (overload) must be

BOX 7.7 Case Example of an Exercise Stress Test

Mr. Smith is a 55-year-old sedentary man with a history of chest pain with exertion. He has undergone a stress test to assist in evaluating his angina. He is not taking any medications at the present time. He has been a smoker for 20 years.

- Resting electrocardiogram (ECG): normal
- Resting heart rate: 75 beats/min
- Age-predicted maximum heart rate: 165 beats/min
- Resting blood pressure: 128/86
- Resting respiration rate: 20 breaths/min
- Treadmill: Bruce protocol

Stage	Heart Rate	Blood Pressure	Comments
1	80		
	84		
	85	138/88	No complaints
2	88		
	90		
	92	142/90	No complaints
3	98		
	100		
	102	156/91	Complaining of leg fatigue
4	114		
	116		
	122	161/90	Complaining of minimal chest pain
5	133		
	135		
	137	174/89	Complaining of severe chest pain; test terminated

Conclusion

The stress test was terminated because of complaints of severe chest pain accompanied by a drop in the ST segment of the ECG to 4 mm. The symptom-limited maximum heart rate was determined to be 137 beats/min. Maximum oxygen consumption was determined to be 32 mL/kg/min.

above the training stimulus threshold (the stimulus that elicits a training or conditioning response) for adaptation to occur.

Once adaptation to a given load has taken place, the training intensity (exercise load) must be increased for the individual to achieve further improvement. Training stimulus thresholds are variable, depending on the individual's level of health, level of activity, age, and gender. The higher the initial level of fitness, the greater the intensity of exercise needed to elicit a change.

A conditioning response occurs generally at 60% to 90% maximum heart rate (50% to 85% $VO_{2\,max}$) depending on the individual and the initial level of fitness.

- Seventy percent maximum heart rate is a minimal-level stimulus for eliciting a conditioning response in healthy young individuals.
- Sedentary or "deconditioned" individuals respond to a low exercise intensity, 40% to 50% of $VO_{2\,max}$.
- The exercise does not have to be exhaustive to achieve a training response.
- Determining the *maximum heart rate* and the *exercise heart rate* for training programs provides the basis for the initial intensity of the exercise (Box 7.8).
- When the individual is young and healthy, the *maximum heart rate* can be determined directly from a maximum performance multistage test, extrapolated from a heart rate achieved on a predetermined submaximum test or, less accurately, calculated as 220 minus age.
- The *exercise heart rate* is determined in one of two ways: (1) as a percentage of the maximum heart rate (the percentage used is dependent on the level of fitness of the individual);

BOX 7.8 Methods to Determine Maximum Heart Rate and Exercise Heart Rate

Determine Maximum Heart Rate (HR)
- From multistage test (for young and healthy)
- HR achieved in predetermined submaximum test
- 220 minus age (less accurate)

Determine Exercise Heart Rate
- Percentage of maximum heart rate (dependent on level of fitness)
- Karvonen's formula (heart rate reserve)

Exercise heart rate = HR_{rest}+ 60–70% (HR_{max} - HR_{rest})

or (2) using the heart rate reserve (Karvonen's formula). Karvonen's formula is based on the heart rate reserve (HRR), which is the difference between the resting heart rate (HR_{rest}) and the maximum heart rate (HR_{max}). The exercise heart rate is determined as a percentage (usually 60% to 70%) of the heart rate reserve plus the resting heart rate (see Box 7.8).
- When using Karvonen's formula, the exercise heart rate is higher than when using the maximum heart rate alone.

Individuals at Risk

Maximum heart rate and exercise heart rate used for the exercise prescription for individuals at risk for coronary artery disease, individuals with coronary artery disease or other chronic disease, and individuals who are elderly are ideally identified based on their performance on the stress test. The maximum heart rate cannot be determined in the same manner as for the young and healthy.

- Assuming that an individual has an average maximum heart rate, using the formula 220 minus age produces substantial errors in prescribing the exercise intensity for these individuals.
- Maximum heart rate, which may be symptom-limited, is considered maximum. At no time should the exercise heart rate exceed the symptom-limited heart rate achieved on the exercise test.
- Individuals with cardiopulmonary disease may start exercise programs, depending on their diagnosis, as low as 40% to 60% of their maximum heart rate.

Variables

Exercising at a high-intensity for a shorter period of time appears to elicit a greater improvement in $VO_{2\,max}$ than exercising at a moderate intensity for a longer period of time. However, as exercise approaches the maximum limit, there is an increase in the relative risk of cardiovascular complications and the risk of musculoskeletal injury.

- The higher the intensity and the longer the exercise intervals, the faster the training effect.
- Maximum oxygen consumption ($VO_{2\,max}$) is the best measure of exercise intensity. Aerobic capacity and heart rate are linearly related; therefore, the maximum heart rate is a function of intensity.

Specificity Principle

The specificity principle as related to the specificity of training refers to adaptations in metabolic and physiological systems depending on the demand imposed. There is no overlap when training for strength-power activities and training for endurance activities. Workload and work-rest periods are selected so training results in:

- Muscle strength without a significant increase in total oxygen consumption.
- Aerobic or endurance training without training the anaerobic systems.
- Anaerobic training without training the aerobic systems.
- Aerobic training specific to the type of activity. When training for swimming events, the individual may not demonstrate an improvement in $VO_{2\,max}$ when running.

Time (Duration)

The optimal duration of exercise for cardiovascular conditioning is dependent on the total work performed, exercise intensity and frequency, and fitness level. Generally speaking, the greater the intensity of the exercise, the shorter the duration needed for adaptation; and the lower the intensity of exercise, the longer the duration needed.

A 20- to 30-minute session is generally optimal at 60% to 70% maximum heart rate. When the intensity is below the heart rate threshold, a 45-minute continuous exercise period may provide the appropriate overload. With high-intensity exercise, 10- to 15-minute exercise periods are adequate; three 5-minute daily periods are effective in some deconditioned patients.

Type (Mode)

Many types of activity provide the stimulus for improving cardiorespiratory fitness. The important factor is that the exercise involves *large muscle groups* that are activated in a *rhythmic, aerobic* nature. However, the magnitude of the changes may be determined by the mode used.

For specific aerobic activities, such as cycling and running, the overload must use the muscles required by the activity and stress the cardiorespiratory system (specificity principle). If endurance of the upper extremities is needed to perform activities on the job, the upper extremity muscles must be targeted in the exercise program. The muscles trained develop a greater oxidative capacity with an increase in blood flow to the area. The increase in blood flow is due to increased microcirculation and more effective distribution of the cardiac output.

Training benefits are optimized when programs are planned to meet the individual needs and capacities of the participants. The skill of the individual, variations among individuals in competitiveness and aggressiveness, and variation in environmental conditions must be considered.

Reversibility Principle

The beneficial effects of exercise training are transient and reversible.

- Detraining occurs rapidly when a person stops exercising. After only 2 weeks of detraining, significant reductions in

work capacity can be measured, and improvements can be lost within several months. A similar phenomenon occurs with individuals who are confined to bed with illness or disability: the individual becomes severely deconditioned, with loss of the ability to carry out normal daily activities as a result of inactivity.
- The frequency or duration of physical activity required to maintain a certain level of aerobic fitness is less than that required to improve it.

CLINICAL TIP

In 2007, ACSM and the American Heart Association (AHA) published recommendations for physical activity for adults and older adults.[6,13] In addition, the CDC and Surgeon General[4] have also specified the amount of physical activity for children, adults, and older adults. Following are the general recommendations for aerobic physical activity:

- ***Children age 6 to 17***: 60 minutes of moderate to vigorous aerobic physical activity per day.
- ***Adults age 18 to 65***: 30 minutes of moderate intensity activity (3–6 MET level) 5 days/week or 20 minutes of vigorous intensity activity (>6 METs) 3 days/week, or acombination of moderate and vigorous intensity. The 30-minute total of moderate intensity can be accumulated in small bouts of continuous activity of at least 10 minutes.
- Older adults age 65 or older (or adults 50 to 65 with chronic health conditions): 30 minutes of moderate intensity activity 5 days/week or 20 minutes of vigorous intensity activity 3 days/week, or a combination of moderate and vigorous intensity. The 30-minute total of moderate intensity can be accumulated in small bouts of continuous activity of at least 10 minutes.

The adult criteria are based on MET level. The older adult criteria for moderate or vigorous intensity are based on a 10 point scale, where 0 is sitting and 10 is working as hard as you can. Moderate intensity activity would be a 5–6 and vigorous activity would be 7–8.

NOTE: Doing more than the minimum described above for adults and older adults is recommended for achieving additional health benefits.

Exercise Program

A carefully planned exercise program can result in higher levels of fitness for the healthy individual, slow the decrease in functional capacity of the elderly, and recondition those who have been ill or have chronic disease. There are three components of the exercise program: (1) a warm-up period; (2) the aerobic exercise period; and (3) a cool-down period.

Warm-Up Period

Physiologically, a time lag exists between the onset of activity and the bodily adjustments needed to meet the physical requirements of the body. The purpose of the warm-up period is to enhance the numerous adjustments that must take place before physical activity.

Physiological Responses

During this period there is:

- An increase in muscle temperature. The higher temperature increases the efficiency of muscular contraction by reducing muscle viscosity and increasing the rate of nerve conduction.
- An increased need for oxygen to meet the energy demands for the muscle. Extraction from hemoglobin is greater at higher muscle temperatures, facilitating the oxidative processes at work.
- Dilatation of the previously constricted capillaries with increases in the circulation, augmenting oxygen delivery to the active muscles and minimizing the oxygen deficit and the formation of lactic acid.
- Adaptation in sensitivity of the neural respiratory center to various exercise stimulants.
- An increase in venous return. This occurs as blood flow is shifted centrally from the periphery.

Purposes

In addition to the physiological responses, the warm-up also prevents or decreases the susceptibility of the musculoskeletal system to injury and the occurrence of ischemic electrocardiographic (ECG) changes and arrhythmias.

Guidelines

The warm-up should be gradual and sufficient to increase muscle and core temperature without causing fatigue or reducing energy stores. Characteristics of the period include:

- A 10-minute period of total body movement exercises, such as calisthenics and walking slowly.
- Attaining a heart rate that is within 20 beats/min of the target heart rate.

Aerobic Exercise Period

The aerobic exercise period is the conditioning part of the exercise program. Attention to the determinants of frequency, intensity, time, and type of the program, as previously discussed, has an impact on the effectiveness of the program. The main consideration when choosing a specific method of training is that the intensity be great enough to stimulate an increase in stroke volume and cardiac output and to enhance local circulation and aerobic metabolism in the appropriate muscle groups. The exercise period must be within the person's tolerance, above the threshold level for adaptation to occur, and below the level of exercise that evokes clinical symptoms.

In aerobic exercise, submaximal, rhythmic, repetitive, dynamic exercise of large muscle groups is emphasized.

There are four methods of training that challenge the aerobic system: continuous, interval (work relief), circuit, and circuit interval.

Continuous Training

- A submaximum energy requirement, sustained throughout the training period, is imposed.
- Once the steady state is achieved, the muscle obtains energy by means of aerobic metabolism. Stress is placed primarily on the slow-twitch fibers.
- The activity can be prolonged for 20 to 60 minutes without exhausting the oxygen transport system.
- The work rate is increased progressively as training improvements are achieved. Overload can be accomplished by increasing the exercise duration.
- In the healthy individual, continuous training is the most effective way to improve endurance.

Interval Training

With this type of training, the work or exercise is followed by a properly prescribed relief or rest interval. Interval training is perceived to be less demanding than continuous training. In the healthy individual, interval training tends to improve strength and power more than endurance.

- The relief interval is either a rest relief (passive recovery) or a work relief (active recovery), and its duration ranges from a few seconds to several minutes. Work recovery involves continuing the exercise but at a reduced level from the work period. During the relief period, a portion of the muscular stores of ATP and the oxygen associated with myoglobin that were depleted during the work period are replenished by the aerobic system; an increase in $VO_{2\ max}$ occurs.
- The longer the work interval, the more the aerobic system is stressed. With a short work interval, the duration of the rest interval is critical if the aerobic system is to be stressed (a work/recovery ratio of 1:1 to 1:5 is appropriate). A rest interval equal to one and a half times the work interval allows the succeeding exercise interval to begin before recovery is complete and stresses the aerobic system. With a longer work interval, the duration of the rest is not as important.
- A significant amount of high-intensity work can be achieved with interval or intermittent work if there is appropriate spacing of the work-relief intervals. The total amount of work that can be completed with intermittent work is greater than the amount of work that can be completed with continuous training.

Circuit Training

Circuit training employs a series of exercise activities. At the end of the last activity, the individual starts from the beginning and again moves through the series. The series of activities is repeated several times.

- Several exercise modes can be used involving large and small muscle groups and a mix of static or dynamic effort.
- Use of circuit training can improve strength and endurance by stressing both the aerobic and anaerobic systems.

Circuit-Interval Training

- Combining circuit and interval training is effective because of the interaction of aerobic and anaerobic production of ATP.
- In addition to the aerobic and anaerobic systems being stressed by the various activities, with the relief interval, there is a delay in the need for glycolysis and the production of lactic acid prior to the availability of oxygen supplying the ATP.

Cool-Down Period

The cool-down period is similar to the warm-up period in that it should last 5 to 10 minutes and consist of total-body movements and static stretching.

The purpose of the cool-down period is to:

- Prevent pooling of the blood in the extremities by continuing to use the muscles to maintain venous return.
- Prevent fainting by increasing the return of blood to the heart and brain as cardiac output and venous return decreases.
- Enhance the recovery period with the oxidation of metabolic waste and replacement of the energy stores.
- Prevent myocardial ischemia, arrhythmias, or other cardiovascular complications.

Application

Application of aerobic training is summarized in Box 7.9.

Physiological Changes that Occur with Training

Changes in the cardiovascular and respiratory systems as well as changes in muscle metabolism occur following endurance training. These changes are reflected both at rest and with exercise. It is important to note that all of the following training effects cannot result from one training program.

Cardiovascular Changes

Changes at Rest

- A reduction in the resting pulse rate occurs in some individuals because of a decrease in sympathetic drive, with decreasing levels of norepinephrine and epinephrine; a decrease in atrial rate secondary to biochemical changes in the muscles and levels of acetylcholine, norepinephrine, and epinephrine in the atria; and an apparent increase in parasympathetic (vagal) tone secondary to decreased sympathetic tone.

BOX 7.9 General Guidelines for an Aerobic Training Program

- Establish the target heart rate and maximum heart rate.
- Warm-up gradually for 5 to 10 minutes. Include stretching and repetitive motions at slow speeds, gradually increasing the effort.
- Increase the pace of the activity so the target heart rate can be maintained for 20 to 30 minutes. Examples include fast walking, running, bicycling, swimming, cross-country skiing, and aerobic dancing.
- Cool-down for 5 to 10 minutes with slow, total body repetitive motions and stretching activities.
- The aerobic activity should be undertaken three to five times per week.
- To avoid injuries from stress, use appropriate equipment, such as correct footwear, for proper biomechanical support. Avoid running, jogging, or aerobic dancing on hard surfaces such as asphalt and concrete.
- To avoid overuse syndromes in structures of the musculoskeletal system, proper warm-up and stretching of muscles to be used should be performed. Progression of activities should be within the tolerance of the individual. Overuse commonly occurs when there is an increase in time or effort without adequate rest (recovery) time between sessions. Increase the repetitions or the time by no more than 10% per week. If pain begins while exercising or lasts longer than 2 hours after exercising, heed the warning and reduce the stress.
- Individualize the program of exercise. All people are not at the same fitness level and therefore, cannot perform the same exercises. Any one exercise has the potential to be detrimental if attempted by someone not able to execute it properly. During recovery following an injury or surgery, choose an exercise that does not stress the vulnerable tissue. Begin at a safe level for the individual and progress as the individual meets the desired goals.

- *A decrease in blood pressure* occurs in some individuals with a decrease in peripheral vascular resistance. The largest decrease is in systolic blood pressure and is most apparent in hypertensive individuals.
- *An increase in blood volume and hemoglobin* may occur. This facilitates the oxygen delivery capacity of the system.

Changes During Exercise

- A reduction in the pulse rate occurs in some individuals because of the mechanisms listed earlier in this section.
- *Increased stroke volume* may occur because of an increase in myocardial contractility and an increase in ventricular volume.
- *Increased cardiac output* may occur as a result of the increased stroke volume that occurs with maximum exercise but not with submaximum exercise. The magnitude of the change is directly related to the increase in stroke volume and the magnitude of the reduced heart rate.
- *Increased extraction of oxygen by the working muscle* occurs in some individuals because of enzymatic and biochemical changes in the muscle, as well as increased maximum oxygen uptake ($VO_{2\ max}$). Greater $VO_{2\ max}$ results in a greater work capacity. The increased cardiac output increases the delivery of oxygen to the working muscles. The increased ability of the muscle to extract oxygen from the blood increases the utilization of the available oxygen.
- *Decreased blood flow per kilogram of the working muscle* may occur even though increasing amounts of blood are shunted to the exercising muscle. The increase in extraction of oxygen from the blood compensates for this change.
- *Decreased myocardial oxygen consumption (pulse rate times systolic blood pressure) for any given intensity of exercise* may occur as a result of a decreased pulse rate with or without a modest decrease in blood pressure. The product can be decreased significantly in the healthy subject without any loss of efficiency at a specific workload.

Respiratory Changes

Changes at Rest

- *Larger lung volumes* develop because of improved pulmonary function, with no change in tidal volume.
- *Larger diffusion capacities* develop because of larger lung volumes and greater alveolar-capillary surface area.

Changes During Exercise

- Larger diffusion capacities occur for the same reasons as those listed previously; the maximum capacity of ventilation is unchanged.
- A smaller amount of air is ventilated at the same oxygen consumption rate; maximum diffusion capacity is unchanged.
- The maximal minute ventilation is increased.
- Ventilatory efficiency is increased.

Metabolic Changes

Changes at Rest

- Muscle hypertrophy and increased capillary density occurs.
- The number and size of mitochondria are increased, increasing the capacity to generate ATP aerobically.

- The muscle myoglobin concentration increases, increasing the rate of oxygen transport and possibly the rate of oxygen diffusion to the mitochondria.

Changes During Exercise

- A decreased rate of depletion of muscle glycogen at submaximum work levels may occur. Another term for this phenomenon is glycogen sparing. It is due to an increased capacity to mobilize and oxidize fat and increased fat-mobilizing and fat-metabolizing enzymes.
- Lower blood lactate levels at submaximal work may occur. The mechanism for this is unclear; it does not appear to be related to decreased hypoxia of the muscles.
- Less reliance on phosphocreatine (PC) and ATP in skeletal muscle and an increased capability to oxidize carbohydrate may result because of an increased oxidative potential of the mitochondria and an increased glycogen storage in the muscle.

NOTE: Ill health may influence metabolic adaptations to exercise.

Other System Changes

Changes in other systems that occur with training include:

- Decrease in body fat.
- Decrease in blood cholesterol and triglyceride levels.
- Increased heat acclimatization.
- Increase in the breaking strength of bones and ligaments and the tensile strength of tendons.

FOCUS ON EVIDENCE

Mark and Janssen[10] examined the amount of physical activity in 1,170 children aged 8 to 17 and the risk of developing hypertension. The odds ratio for developing hypertension in children who met the CDC guideline of 60 minutes of moderate to vigorous activity per day was 0.38 (95% CI 0.17 to 0.52) compared to no physical activity.

Lovell, Cuneo, and Gass[9] assessed the effect of aerobic activity performed with Cycle ergometry on VO_{2max}, leg strength and power in men age 70 to 80 years old who were not participating in regular physical activity. Frequency of training was 3 days/week, intensity was 50% to 70% of VO_{2max}, and the time of the training was 16 weeks followed by an additional 4 weeks of no training. There was a significant increase ($p<0.05$) in VO_{2max}, leg strength, and power following the active training.

These gains were lost, however, following the final 4 weeks of no training (VO_{2max} remained above pretraining levels but had decreased).

Application of Principles of an Aerobic Conditioning Program for the Patient with Coronary Disease

Employing the principles of aerobic conditioning in physical therapy has been most dominant in program planning for the individual following a myocardial infarction (MI) or following coronary artery bypass surgery.[5,7,8]

During the past 20 to 25 years, there have been major changes in the medical management of these patients. The changes have included shortened hospital stays, more aggressive progression of activity for the patient following MI or cardiac surgery, and earlier initiation of an exercise program based on a low-level stress test prior to discharge from the hospital. An aerobic conditioning program, in addition to risk factor modification, is a dominant part of cardiac rehabilitation.

Inpatient Phase (Phase I)

The inpatient phase of the program occurs in the hospital following stabilization of the patient's cardiovascular status after MI or coronary bypass surgery, and generally lasts 3 to 5 days.

Purpose

The purpose of the early portion of cardiac rehabilitation is to:

- Initiate risk factor education and address future modification of certain behaviors, such as eating habits and smoking.
- Initiate self-care activities and progress from sitting to standing to minimize deconditioning (1 to 3 days postevent).
- Provide an orthostatic challenge to the cardiovascular system (3 to 5 days postevent). This is usually accomplished by supervised ambulation. Ambulation is usually monitored electrocardiographically, as well as manually monitoring the heart rate, ventilation rate, and blood pressure.
- Prepare patients and family for continued rehabilitation and for life at home after a cardiac event.

Outpatient Phase (Phase II)

The outpatient phase of the program is initiated either upon discharge from the hospital or, depending on the severity of the diagnosis, 6 to 8 weeks later. This delay allows time for the myocardium to heal as well as time to monitor the patient's response to a new medical regimen. Participants are monitored via telemetry to determine heart rate and rhythm responses; blood pressure is recorded at rest and during

exercise; and ventilation responses are noted. These programs usually last 6 to 8 weeks (Box 7.10).

Purpose

The purpose of the program is to:

- Increase the person's exercise capacity in a safe, progressive manner, so adaptive cardiovascular and muscular changes occur. The early part of the program is referred to by some as "low-level" exercise training.
- Enhance cardiac functions and reduce the cardiac cost of work. This may help eliminate or delay symptoms such as angina and ST-segment changes in the patient with coronary heart disease.
- Produce favorable metabolic changes.
- Determine the effect of medications on increasing levels of activity.
- Relieve anxiety and depression.
- Progress the patient to an independent exercise program.

Guidelines

A symptom-limited exercise stress test is performed 6 to 12 weeks after hospital discharge (or as early as 2 to 4 weeks following discharge).

The exercise program is predominantly aerobic. Generally, for patients with functional capacities greater than 5 METs, the exercise prescription is based on the results of the symptom-limited test.

Frequency. Participants often attend sessions offered three times per week.

Intensity. The initial level of activity or training intensity may be as low as 40% to 60% of the maximum heart rate or 40% to 70% of the functional capacity defined in METs. The starting intensity is dictated by the severity of the diagnosis in concert with the individual's age and prior fitness level. The intensity is progressed as the individual responds to the training program.

Time. The duration of the exercise session may be limited to 10 to 15 minutes at the start, progressing to 30 to 60 minutes as the patient's status improves. Each session usually includes 8- to 10-minute warm-up and cool-down periods.

Type. The mode of exercise is usually continuous, using large muscle groups, such as stationary biking or walking. These activities allow ECG monitoring via telemetry.

Method. Circuit-interval exercise is a common method used with the patient during phase II. The patient can exercise on each modality at a defined workload, compared with exercising continuously on a bicycle or treadmill. As a result, the patient can:

- Perform more physical work.
- Exercise at a higher intensity—fitness may improve within a shorter period of time.
- Maintain lactic acid and the oxygen deficit at minimum levels.
- Exercise at a lower rate of perceived exertion.

Weight training. Low-level weight training may be initiated during the outpatient program, provided the individual has undergone a symptom-limited stress test. Resistive exercises should not produce ischemic symptoms associated with an increase in heart rate and systolic blood pressure. Therefore, heart rate and blood pressure should be monitored periodically throughout the exercise session. Starting weight may be calculated using 40% of a one repetition maximum (1-RM) effort.

Progression. Progression of the workload occurs when there have been three consecutive sessions (every-other-day sessions) during which the peak heart rate is below the target heart rate.

BOX 7.10 Case Example of a Cardiac Rehabilitation Referral

Mr. Smith is referred and undergoes further evaluation to determine the cause of his chest pain. He is diagnosed with single vessel coronary artery disease. He is referred to cardiac rehabilitation.

- Medications. Nitroglycerin as needed to relieve angina. Mr. Smith will attend cardiac rehabilitation three times per week for 8 to 12 weeks to improve his fitness level and attend smoking cessation classes. He will meet with a medical dietitian to discuss meal planning to lower his intake of fat and cholesterol.
- Exercise prescription. Mr. Smith will exercise at an intensity lower than his anginal threshold. This intensity will be initially established at 60% to 65% of his maximum heart rate or 50% of his $VO_{2\ max}$. He will exercise three times per week for 20 to 40 minutes, depending on his tolerance.

Outpatient Program (Phase III)

The outpatient phase of cardiac rehabilitation includes a supervised exercise conditioning program, which is often continued in a hospital or community setting. Heart rate and rhythm are no longer monitored via telemetry. Participants are reminded to monitor their own pulse rate, and a supervisory person is available to monitor blood pressure.

Purpose

The purpose of the program is to continue to improve or maintain fitness levels achieved during the phase II program.

Guidelines

Recreational activities. Activities to maintain levels gained during phase II may include:

- Swimming, which incorporates both arms and legs. However, there is a decreased awareness of ischemic symptoms while swimming, especially when the skill level is poor.
- Outdoor hiking, which is excellent if on level terrain.

Activities at 8 METs

- Jogging approximately 5 miles per hour
- Cycling approximately 12 miles per hour
- Vigorous downhill skiing

Special Considerations

There are special considerations related to types of exercise and patient needs that must be recognized when developing conditioning programs for patients with coronary disease. Arm exercises elicit different responses than leg exercises.

- Mechanical efficiency based on the ratio between output of external work and caloric expenditure is lower than with leg exercises.
- Oxygen uptake at a given external workload is significantly higher for arm exercises than for leg exercises.
- Myocardial efficiency is lower with leg exercises than with arm exercises.
- Myocardial oxygen consumption (heart rate × systolic blood pressure) is higher with arm exercises than with leg exercises.

PRECAUTION: Patients with coronary disease complete 35% less work with arm exercises than with leg exercises before symptoms occur.

Adaptive Changes

Adaptive changes following training of individuals with cardiac disease include:

- Increased myocardial aerobic work capacity.
- Increased maximum aerobic or functional capacity by predominantly widening the a-vO_2 difference.
- Increased stroke volume following high-intensity training 6 to 12 months into the training program.
- Decreased myocardial demand for oxygen.
- Increased myocardial supply by the decreased heart rate and prolongation of diastole.
- Increased tolerance to a given physical workload before angina occurs.
- Significantly lower heart rate at each submaximum workload and, therefore, a greater heart rate reserve. When muscles are used that are not directly involved in the activity, the reduction in heart rate is not as great.
- Improved psychological orientation and, over time, an impact on depression scores, scores for hysteria, hypochondriasis, and psychoasthenia on the Minnesota Multiphasic Personality Inventory.

CLINICAL TIP

Cardiovascular complications are prevented and/or reduced if the program includes appropriate selection of patients, continuous evaluation of each patient, medical supervision of the exercise throughout the training period, regular communication with the physician, specific instructions to patients about adverse symptoms, class size limitations to 30 or fewer patients, and maintenance of accurate records related to compliance to the program.

Applications of Aerobic Training for the Deconditioned Individual and the Patient with Chronic Illness

Deconditioned individuals, including those with chronic illness and the elderly, may have major limitations in pulmonary and cardiovascular reserves that severely curtail their daily activities.

Deconditioning

Implications of the changes due to deconditioning brought on by inactivity resulting from any illness or chronic disease are important to remember.

- There is decreased work capacity, which is a result of decreased maximum oxygen uptake and decreased ability to use oxygen and perform work. There is also decreased cardiac output, which is the major limiting factor.
- There is decreased circulating blood volume that can be as much as 700 to 800 mL. For some individuals, this results in tachycardia along with orthostatic hypotension, dizziness, and episodes of syncope when initially attempting to stand.
- There is a decrease in plasma and red blood cells, which increases the likelihood of life-threatening embothrombolic episodes and prolongation of the convalescent period.
- There is a decrease in lean body mass, which results in decreased muscle size and decreased muscle strength and ability to perform activities requiring large muscle groups. For example, the individual may have difficulty walking with crutches or climbing stairs.
- There is increased excretion of urinary calcium, which results from a decrease in the weight-bearing stimulus critical in maintaining bone integrity, in bone loss or osteoporosis, and in an increased likelihood of fractures upon falling because of osteoporosis.

Reversal of Deconditioning

Through an exercise program, the negative cardiovascular, neuromuscular, and metabolic functions can be reversed. This results in:

- A decrease in the resting heart rate, the heart rate with any given exercise load, and urinary excretion of calcium.
- An increase in stroke volume at rest, stroke volume with exercise, cardiac output with exercise, total heart volume, lung volume (ventilatory volume), vital capacity, maximum

oxygen uptake, circulating blood volume, plasma volume and red blood cells, and lean body mass.

- A reversal of the negative nitrogen and protein balance.
- An increase in levels of mitochondrial enzymes and energy stores.
- Less use of the anaerobic systems during activity.

Adaptations for Participation Restrictions (Disabilities), Activity Restrictions (Functional Limitations), and Deconditioning

Individuals who have participation or activity restrictions should not be excluded from a conditioning program that can increase their fitness level. This includes individuals in wheelchairs or persons who have problems ambulating, such as those with paraplegia, hemiplegia, or amputation, and those with an orthopedic problem, such as arthrodesis.

- Adaptations must be made when testing the physically disabled using a wheelchair treadmill or, more frequently, using the upper extremity ergometer.
- Exercise protocols may emphasize upper extremities and manipulation of the wheelchair.
- It is important to remember that energy expenditure is increased when the gait is altered, and wheelchair use is less efficient than walking without impairment.

Impairments, Goals, and Plan of Care

The goals of an aerobic exercise program are dependent on the initial level of fitness of the individual and on his or her specific clinical needs. The general goals are to decrease the deconditioning effects of disease and chronic illness and to improve the individual's cardiovascular and muscular fitness.

Common Impairments

- Increased susceptibility to thromboembolic episodes, pneumonia, atelectasis, and the likelihood of fractures
- Tachycardia, dizziness, and orthostatic hypotension when moving from sitting to standing
- A decrease in general muscle strength, with difficulty and shortness of breath in climbing stairs
- A decrease in work capacity that limits distances walked and activities tolerated
- Increased heart rate and blood pressure responses (rate-pressure product) to various activities
- A decrease in the maximum rate-pressure product tolerated with angina or other ischemic symptoms appearing at low levels of exercise

Goals

- Prevent thromboembolic episodes, pneumonia, atelectasis, and fractures
- Decrease the magnitude of the orthostatic hypotensive response
- Improve ability to climb stairs safely and without shortness of breath
- Develop tolerance for walking longer measured distances and completing activities without fatigue or symptoms
- Decrease heart rate and blood pressure (rate-pressure product) at a given level of activity
- Increase the maximum rate-pressure product tolerated without ischemic symptoms

Outcomes

- Improved pulmonary, cardiovascular, and metabolic response to various levels of exercise
- Improved ability to complete selected activities with appropriate heart rate and blood responses to exercise

Guidelines

Guidelines for establishing a safe program of intervention for the deconditioned individual and the convalescent patient with chronic illness are summarized in Boxes 7.11 and 7.12.

Age Differences

Differences in endurance and physical work capacity among children, young adults, and middle-aged or elderly individuals are evident. Some comparisons are made between maximum oxygen uptake and the factors influencing it and among blood pressure, respiratory rate, vital capacity, and maximum voluntary ventilation in the different age categories. It is important when developing aerobic conditioning programs that these age-related differences are taken into consideration.

BOX 7.11 Guidelines for Initiating an Aerobic Exercise Program for the Deconditioned Individual and the Patient with Chronic Illness

- Determine the exercise heart rate response that can be safely reached using the Karvonen formula as a guide, accounting for medical conditions, medications, and the individual's perceived exertion.
- Initiate a program of activities for the patient that does not elicit a cardiovascular response over the exercise heart rate (e.g., walking, repetitive activities, easy calisthenics).
- Provide patients with clearly written instructions about any activity they perform on their own.
- Initiate an educational program that provides the patient with information about effort symptoms and exercise precautions, monitoring the heart rate, and making modifications when indicated.

BOX 7.12 Guidelines for Progression of an Aerobic Training Program

- Determine the maximum heart rate or symptom-limited heart rate by multistage testing with ECG monitoring.
- Decide on the threshold stimulus (percentage of maximum or symptom-limited heart rate) that elicits a conditioning response for the individual tested and that can be used as the exercise heart rate.
- Determine the frequency, intensity, and time of exercise that results in attaining the exercise heart rate and a conditioning response.
- Determine the type of exercise to be used based on the individual's physical capabilities and interest.
- Initiate an exercise program with the patient and provide clearly written instructions regarding the details of the program.
- Educate the patient about:
  - Effort symptoms and the need to cease or modify exercise when these symptoms appear and to communicate with the physical therapist and/or physician about these problems.
  - Monitoring heart rate at rest as well as during and following exercise.
  - The importance of exercising within the guidelines provided by the physical therapist.
  - The importance of consistent long-term follow-up with the exercise program so it can be progressed within safe limits.
  - The importance of modifying risk factors related to cardiac problems.

Children

Between the ages of 5 and 15 there is a threefold increase in body weight, lung volume, heart volume, and maximum oxygen uptake.

Heart rate. Resting heart rate is on the average above 125 (126 in girls, 135 in boys) at infancy. Resting heart rate drops to adult levels at puberty. Maximum heart rate is age-related (220 minus age).

Stroke volume. Stroke volume is closely related to size. Children 5 to 16 years of age have a stroke volume of 30 to 40 mL.

Cardiac output. Cardiac output is related to size. Cardiac output increases with increasing stroke volume. The increase in cardiac output for a given increase in oxygen consumption is a constant throughout life: it is the same in the child as in the adult.

Arteriovenous oxygen difference. Children tolerate a larger arteriovenous oxygen difference (a-VO_2) than adults. The larger a-VO_2 difference makes up for the smaller stroke volume.

Maximum oxygen uptake. The VO_{2max} increases with age up to 20 years (expressed as liters per minute). Before puberty, girls and boys show no significant difference in maximum aerobic capacity. Cardiac output in children is the same as in the adult for any given oxygen consumption. Endurance times increase with age until 17 to 18 years.

Blood pressure. Systolic blood pressure increases from 40 mm Hg at birth to 80 mm Hg at age 1 month to 100 mm Hg several years before puberty. Adult levels are observed at puberty. Diastolic blood pressure increases from 55 to 70 mm Hg from 4 to 14 years of age, with little change during adolescence.

Respiration. Respiratory rate decreases from 30 breaths per minute at infancy to 16 breaths per minute at 17 to 18 years of age. Vital capacity and maximum voluntary ventilation are correlated with height, although the greater increase in boys than girls at puberty may be due to an increase in lung tissue.

Muscle mass and strength. Muscle mass increases through adolescence, primarily owing to muscle fiber hypertrophy and the development of sarcomeres. Sarcomeres are added at the musculotendinous junction to compensate for the required increase in length. Girls develop peak muscle mass between 16 and 20 years, whereas boys develop peak muscle mass between 18 and 25 years. Strength gains are associated with increased muscle mass in conjunction with neural maturation.

Anaerobic ability. Children generally demonstrate a limited anaerobic capacity. This may be due to a limited amount of phosphofructokinase, a controlling enzyme in the glycolytic pathway. Children produce less lactic acid when performing anaerobically. This may be due to a limited glycolytic capacity.

Young Adults

There are more data on the physiological parameters of fitness for the young and middle-aged adult than for children or the elderly.

Heart rate. Resting heart rate reaches 60 to 65 beats per minute at 17 to 18 years of age (75 beats per minute in a sitting, sedentary young man). Maximum heart rate is age-related (190 beats per minute in the same sedentary young man).

Stroke volume. The adult values for stroke volume are 60 to 80 mL (75 mL in a sitting, sedentary young man). With maximum exercise, stroke volume is 100 mL in that same sedentary young man.

Cardiac output for the sedentary young man at rest. Cardiac output at rest is 75 beats per minute × 75 mL, or 5.6 liters per minute. With maximum exercise, cardiac output is 190 beats per minute × 100 mL, or 19 liters per minute.

Arteriovenous oxygen difference. Approximately 25% to 30% of the oxygen is extracted from blood as it runs through the muscles or other tissues at rest. In a normal, sedentary young man, it increases threefold (5.2 to 15.8 mL/dL blood) with exercise.

Maximum oxygen uptake. The difference in $VO_{2\ max}$ between males and females is greatest in the adult. Differences in $VO_{2\ max}$ between the sexes is minimal when $VO_{2\ max}$ is expressed relative to lean body weight. In the sedentary young man, maximum oxygen uptake equals 3,000 mL/min (oxygen uptake at rest equals 300 mL/min).

Blood pressure. Systolic blood pressure is 120 mm Hg (average). At peak effort during exercise, values may range from as low as 190 mm Hg to as high as 240 mm Hg. Diastolic blood pressure is 80 mm Hg (average). Diastolic pressure does not change markedly with exercise.

Respiration. Respiratory rate is 12 to 15 breaths per minute. Vital capacity is 4,800 mL in a man 20 to 30 years of age. Maximum voluntary ventilation varies considerably from laboratory to laboratory and is dependent on age and the surface area of the body.

Muscle mass and strength. Muscle mass increases with training as a result of hypertrophy. This hypertrophy can be the result of an increased number of myofibrils or increased actin and myosin, sarcoplasm, and/or connective tissue. As the nervous system matures, increased recruitment of motor units or decreased autogenic inhibition by Golgi tendon organs appears also to dictate strength gains.

Anaerobic ability. Anaerobic training increases the activity of several controlling enzymes in the glycolytic pathway and enhances stored quantities of ATP and phosphocreatine. Anaerobic training increases the muscle's ability to buffer the hydrogen ions released when lactic acid is produced. Increased buffering allows the muscle to work anaerobically for longer periods of time.

Older Adults

With increasing interest in the aged, data are appearing in the literature about this age group and their response to exercise.

Heart rate. Resting heart rate is not influenced by age. Maximum heart rate is age-related and decreases with age (in very general terms, 220 minus age). The average maximum heart rate for men 20 to 29 years of age is 190 beats/min. For men 60 to 69 years of age, it is 164 beats/min. The amount that the heart rate increases in response to static and maximum dynamic exercise (hand grip) decreases in the elderly.

Stroke volume. Stroke volume decreases in the aged and results in decreased cardiac output.

Cardiac output. Cardiac output decreases with age as the result of a decrease in stroke volume and other age-related health changes which affect preload and afterload.

Arteriovenous difference. Arteriovenous oxygen difference decreases as a result of decreased lean body mass and low oxygen-carrying capacity.

Maximum oxygen uptake. According to cardiorespiratory fitness classification, if men 60 to 69 years of age of average fitness level are compared with men 20 to 29 years of age of the same fitness level, the maximum oxygen uptake for the older man is lower (20 to 29 years is 31 to 37 mL/kg per minute; 60 to 69 years is 18 to 23 mL/kg per minute). Aerobic capacity decreases about 10% per decade when evaluating sedentary men. Maximum oxygen consumption decreases on an average from 47.7 mL/kg per minute at age 25 years to 25.5 mL/kg per minute at age 75 years. This decrease is not directly the result of age; athletes who continue exercising have significantly less decrease in $VO_{2\ max}$ when evaluated over a 10-year period.

Blood pressure. Blood pressure increases because of increased peripheral vascular resistance (average systolic blood pressure of the aged is 150 mm Hg; average diastolic blood pressure is 90 mm Hg). If the definition of high blood pressure (stage II hypertension) is 160/100, then 22% of men and 34% of women 65 to 74 years of age are hypertensive. Using 150/95 mm Hg as a cutoff, 25% of individuals are hypertensive at age 50 years and 70% between the ages of 85 and 95 years.

Respiration. Respiratory rate increases with age. Vital capacity decreases with age. There is a 25% decrease in the vital capacity of the 50- to 60-year-old man compared with the 20- to 30-year-old man with the same surface area. Maximum voluntary ventilation decreases with age.

Muscle mass and strength. Generally, the strength decline with age is associated with a decrease in muscle mass and physical activity. The decrease in muscle mass is primarily due to a decrease in protein synthesis, in concert with a decline in the number of fast-twitch muscle fibers. Aging may also affect strength by slowing the nervous system's response time. This may alter the ability to recruit motor units effectively. Continued training as one ages appears to reduce the effects of aging on the muscular system.

Independent Learning Activities

Critical Thinking and Discussion

1. A 16-year-old cross-country runner is referred to the clinic at which you are employed with the diagnosis of a right ankle sprain. You examine and evaluate him and develop a treatment plan for the ankle. You must also address his desire to return to competition when able.
   - Discuss the energy systems utilized with distance running.
   - Discuss the notion of sport specificity.
   - What aerobic exercises could the patient do to maintain his aerobic condition while his ankle heals without stressing the ankle?
2. You are an invited speaker at a senior citizen center for a lunchtime discussion of lifetime fitness and establishing an appropriate exercise program for individuals in this age category.
   - Discuss the definition of fitness.
   - Discuss the concept of the exercise prescription.
   - Describe the necessary precautions when dealing with the older population (both the older athlete and the untrained individual).
3. Explain the concepts of energy expenditure, oxygen consumption, and efficiency with regard to ambulating with an assistive device with each of these diagnoses: rheumatoid arthritis, post-tibial fracture, and post-total-hip replacement.
4. Design an exercise program for the local firefighters. Utilize the concepts of the aerobic energy systems, anaerobic energy system, and strength training.
5. You have been invited to speak to a group of elementary and preschool teachers about the importance of aerobic exercise for children. Explain the basic physiological differences between children and adults at rest with regard to heart rate, respiratory rate and metabolism, and their response to exercise.

CHAPTER

8

Exercise for Impaired Balance

ANNE D. KLOOS, PT, PhD, NCS ■ DEBORAH L. GIVENS, PT, PhD, DPT

Loss of balance and falling are problems that affect individuals with a wide range of diagnoses. Physical therapists commonly evaluate balance and use balance training/exercises as either primary or secondary interventions for patients undergoing many types of rehabilitation programs. Because of the importance of balance assessment and treatment in clinical practice, The *Guide to Physical Therapist Practice*[5] has designated an entire preferred practice pattern (pattern 5A) to primary prevention/risk reduction for loss of balance and falling. The purpose of this chapter is to present an overview of key background terms and concepts related to balance, how balance control is normally achieved in humans for a variety of conditions, possible causes of balance impairments, and evidence-based assessments and interventions for enhancing all aspects of an individual's balance control.

Background and Concepts

Balance: Key Terms and Definitions

Balance, or postural stability, is a generic term used to describe the dynamic process by which the body's position is maintained in equilibrium. Equilibrium means that the body is either at rest (static equilibrium) or in steady-state motion (dynamic equilibrium). Balance is greatest when the body's center of mass (COM) or center of gravity (COG) is maintained over its base of support (BOS).

Center of mass. The COM is a point that corresponds to the center of the total body mass and is the point at which the body is in perfect equilibrium. It is determined by finding the weighted average of the COM of each body segment.[135]

Center of gravity. The COG refers to the vertical projection of the center of mass to the ground. In the anatomical position, the COG of most adult humans is located slightly anterior to the second sacral vertebra[14] or approximately 55% of a person's height.[55]

Momentum. Momentum is the product of mass times velocity. Linear momentum relates to the velocity of the body along a straight path, for example, in the sagittal or transverse planes. Angular momentum relates to the rotational velocity of the body.

Base of support. The BOS is defined as the perimeter of the contact area between the body and its support surface; foot placement alters the BOS and changes a person's postural stability.[106] A wide stance, such as is seen with many elderly individuals, increases stability, whereas a narrow BOS, such as tandem stance or walking, reduces it. So long as a person maintains the COG within the limits of the BOS, referred to as the *limits of stability*, he or she does not fall.

Limits of stability. "Limits of stability" refers to the sway boundaries in which an individual can maintain equilibrium without changing his or her BOS (Fig. 8.1).[106] These boundaries are constantly changing depending on the task, the individual's biomechanics, and aspects of the environment.[137] For

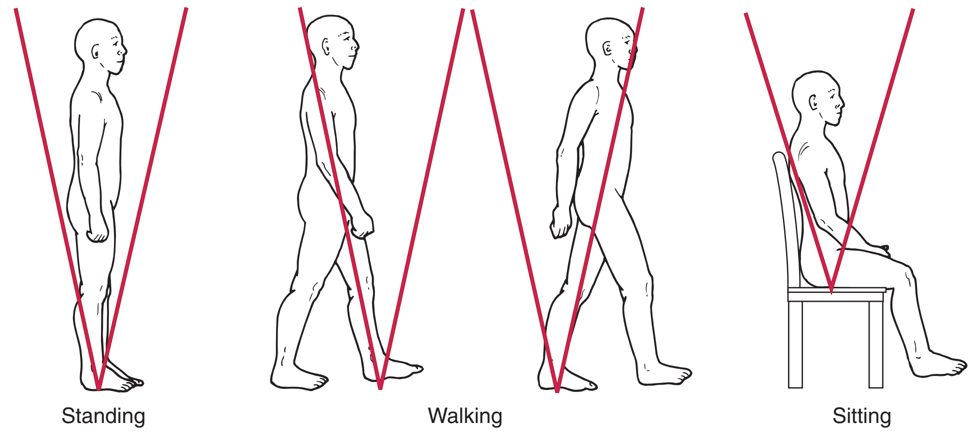

FIGURE 8.1 Boundaries of the limits of stability while standing, walking, and sitting.

example, the limits of stability for a person during quiet stance is the area encompassed by the outer edges of the feet in contact with the ground. Any deviations in the body's COM position relative to this boundary are corrected intermittently, producing a random swaying motion. For normal adults, the anteroposterior sway limit is approximately 12° from the most posterior to most anterior position.[107] Lateral stability varies with foot spacing and height; adults standing with 4 inches between the feet can sway approximately 16° from side to side.[105] However, a person sitting without trunk support has much greater limits of stability than when standing, because the height of the COM above the BOS is less and the BOS is much larger (i.e., perimeter of the buttocks in contact with a surface).

Ground reaction force and center of pressure. In accordance with Newton's law of reaction, the contact between our bodies and the ground due to gravity (action forces) is always accompanied by a reaction from it, the so-called ground reaction force.

The *center of pressure* (COP) is the location of the vertical projection of the ground reaction force.[162] It is equal and opposite to the weighted average of all the downward forces acting on the area in contact with the ground. If one foot is on the ground, the net COP lies within that foot. When both feet are on the ground, the net COP lies somewhere between the two feet, depending on how much weight is taken by each foot. When both feet are in contact, the COP under each foot can be measured separately. To maintain stability, a person produces muscular forces to continually control the position of the COG, which in turn changes the location of the COP. Thus, the COP is a reflection of the body's neuromuscular responses to imbalances of the COG.[163] A force plate is traditionally used to measure ground reaction forces (in Newtons [N]) and COP movements (in meters [m]).

Balance Control

Balance is a complex motor control task involving the detection and integration of sensory information to assess the position and motion of the body in space and the execution of appropriate musculoskeletal responses to control body position within the context of the environment and task. Thus, balance control requires the interaction of the nervous and musculoskeletal systems and contextual effects (Fig. 8.2).

- The *nervous system* provides the (1) sensory processing for perception of body orientation in space provided mainly by the visual, vestibular, and somatosensory systems; (2) sensorimotor integration essential for linking sensation to motor responses and for adaptive and anticipatory (i.e., centrally programmed postural adjustments that precede voluntary movements) aspects of postural control; and (3) motor strategies for planning, programming, and executing balance responses.[60]
- *Musculoskeletal contributions* include postural alignment, musculoskeletal flexibility such as joint range of motion (ROM), joint integrity, muscle performance (i.e., muscle strength, power, and endurance), and sensation (touch, pressure, vibration, proprioception, and kinesthesia).
- *Contextual effects* that interact with the two systems are the environment whether it is closed (predictable with no distractions) or open (unpredictable and with distractions), the support surface (i.e., firm versus slippery, stable versus unstable, type of shoes), the amount of lighting, effects of gravity and inertial forces on the body, and task characteristics (i.e., well-learned versus new, predictable versus unpredictable, single versus multiple tasks).

Even if all elements of the neurological and musculoskeletal systems are operating effectively, a person may fall if contextual effects force the balance control demands to be so high that the person's internal mechanisms are overwhelmed.

Sensory Systems and Balance Control

Perception of one's body position and movement in space require a combination of information from peripheral receptors in multiple sensory systems, including the visual, somatosensory

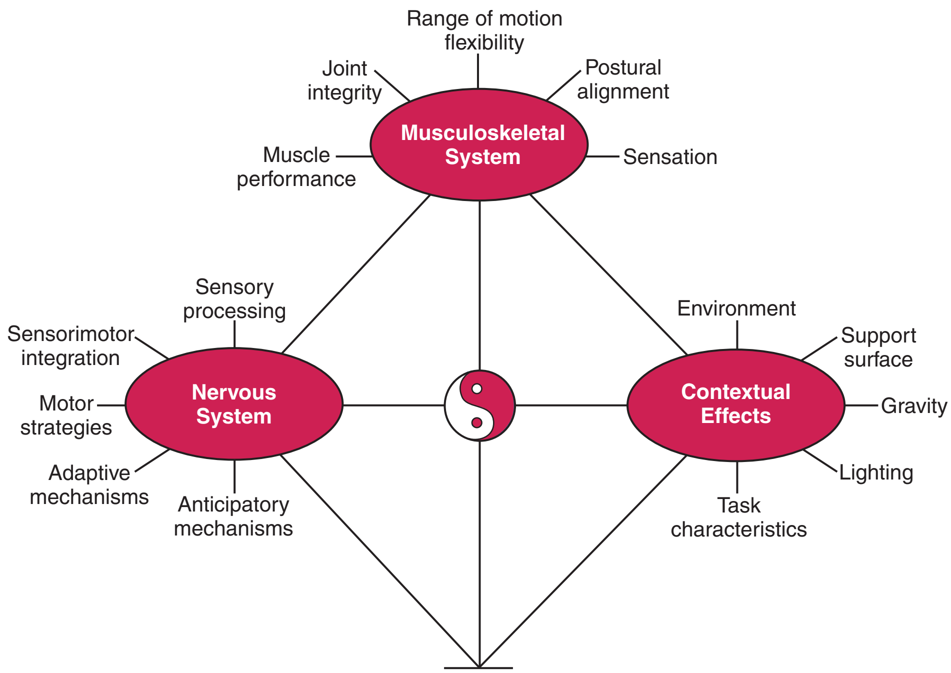

FIGURE 8.2 Interactions of the musculoskeletal and nervous systems and contextual effects for balance control.

(proprioceptive, joint, and cutaneous receptors), and vestibular systems.

Visual System

The visual system provides information regarding (1) the position of the head relative to the environment; (2) the orientation of the head to maintain level gaze; and (3) the direction and speed of head movements, because as your head moves, surrounding objects move in the opposite direction. Visual stimuli can be used to improve a person's stability when proprioceptive or vestibular inputs are unreliable by fixating the gaze on an object. Conversely, visual inputs sometimes provide inaccurate information for balance control, such as when a person is stationary and a large object, such as a nearby bus, starts moving, causing the person to have an illusion of movement.

Somatosensory System

The somatosensory system provides information about the position and motion of the body and body parts relative to each other and the support surface. Muscle proprioceptors, including muscle spindles and Golgi tendon organs (sensitive to muscle length and tension), joint receptors (sensitive to joint position, movement, and stress), and skin mechanoreceptors (sensitive to vibration, light touch, deep pressure, skin stretch), are the dominant sensory inputs for maintaining balance when the support surface is firm, flat, and fixed. However, when standing on a surface that is moving (e.g., on a boat) or on a surface that is not horizontal (e.g., on a ramp), inputs about body position with respect to the surface are not appropriate for maintaining balance; therefore, a person must rely on other sensory inputs for stability in these conditions.[137]

Information from joint receptors does not contribute greatly to conscious joint position sense. It has been demonstrated that local anesthetization of joint tissues and total joint replacement does not impair joint position awareness.[50,51] Muscle spindle receptors appear to be mostly responsible for providing joint position sense, whereas the primary role of joint receptors is to assist the gamma motor system in regulating muscle tone and stiffness to provide anticipatory postural adjustments and to counteract unexpected postural disturbances.[113]

Vestibular System

The vestibular system provides information about the position and movement of the head with respect to gravity and inertial forces. Receptors in the semicircular canals (SCCs) detect angular acceleration of the head, whereas the receptors in the otoliths (utricle and saccule) detect linear acceleration and head position with respect to gravity. The SCCs are particularly sensitive to fast head movements, such as those made during walking or during episodes of imbalance (slips, trips, stumbles), whereas the otoliths respond to slow head movements, such as during postural sway.[59,137]

By itself, the vestibular system can give no information about the position of the body. For example, it cannot distinguish a simple head nod (head movement on a stable trunk) from a forward bend (head movement in conjunction with a moving trunk).[59] Consequently, additional information, particularly from mechanoreceptors in the neck, must be provided for the central nervous system (CNS) to have a true picture of the orientation of the head relative to the body.[113]

The vestibular system uses motor pathways originating from the vestibular nuclei for postural control and coordination of eye and head movements. The vestibulospinal reflex brings about postural changes to compensate for tilts and movements of the body through vestibulospinal tract projections to antigravity muscles at all levels of the spinal cord. The vestibulo-ocular reflex stabilizes vision during head and body movements through projections from the vestibular nuclei to the nuclei that innervate extraocular muscles.

Sensory Organization for Balance Control

Vestibular, visual, and somatosensory inputs are normally combined seamlessly to produce our sense of orientation and movement.[113] Incoming sensory information is integrated and processed in the cerebellum, basal ganglia, and supplementary motor area.[161] Somatosensory information has the fastest processing time for rapid responses, followed by visual and vestibular inputs.[161] When sensory inputs from one system are inaccurate owing to environmental conditions or injuries that decrease the information-processing rate, the CNS must suppress the inaccurate input and select and combine the appropriate sensory inputs from the other two systems. This adaptive process is called *sensory organization*. Most individuals can compensate well if one of the three systems is impaired; therefore, this concept is the basis for many treatment programs.

Types of Balance Control

Functional tasks require different types of balance control, including (1) static balance control to maintain a stable antigravity position while at rest, such as when standing and sitting; (2) dynamic balance control to stabilize the body when the support surface is moving or when the body is moving on a stable surface, such as sit-to-stand transfers or walking; and (3) automatic postural reactions to maintain balance in response to unexpected external perturbations, such as standing on a bus that suddenly accelerates forward.

- *Feedforward (open loop motor control)* is utilized for movements that occur too fast to rely on sensory feedback (e.g., reactive responses) or for anticipatory aspects of postural control.
- *Anticipatory control* involves activation of postural muscles in advance of performing skilled movements, such as activation of posterior leg and back extensor muscles prior to a person pulling on a handle when standing[30] or planning how to navigate to avoid obstacles in the environment.
- *Closed loop control* is utilized for precision movements that require sensory feedback (e.g., maintaining balance while sitting on a ball or standing on a balance beam).

Motor Strategies for Balance Control

To maintain balance, the body must continually adjust its position in space to keep the COM of an individual over the BOS or to bring the COM back to that position after a perturbation. Horak and Nashner[61] described three primary movement strategies used by healthy adults to recover balance in response to sudden perturbations of the supporting surface (i.e., brief anterior or posterior platform displacements) called ankle, hip, and stepping strategies (Fig. 8.3). Factors that determine which strategy most effectively addresses a balance disturbance are identified in Box 8.1. Results of research examining the patterns of muscle activity underlying these

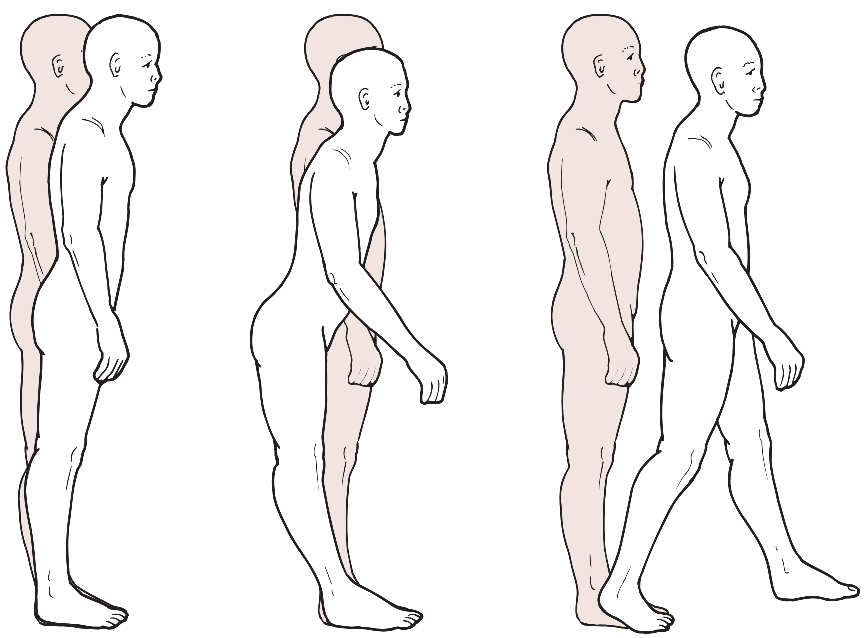

FIGURE 8.3 Ankle, hip, and stepping strategies used by adults to control body sway.

BOX 8.1 Factors Influencing Selection of Balance Strategies

- Speed and intensity of the displacing forces
- Characteristics of the support surface
- Magnitude of the displacement of the center of mass
- Subject's awareness of the disturbance
- Subject's posture at the time of perturbation
- Subject's prior experiences

movement strategies suggest that preprogrammed muscle synergies comprise the fundamental movement unit used to restore balance.[61,103,108] A *synergy* is a functional coupling of groups of muscles, so they must act together as a unit; this organization greatly simplifies the control demands of the CNS.

The CNS uses three movement systems to regain balance after the body is perturbed: reflex, automatic, and voluntary systems. Table 8.1 summarizes the key characteristics of reflexes, automatic postural responses, and voluntary movements.[105]

- "*Stretch*" *reflexes* mediated by the spinal cord comprise the first response to external perturbations. They have the shortest latencies (<70 ms), are independent of task demands, and produce stereotyped muscle contractions in response to sensory inputs.
- *Voluntary responses* have the longest latencies (>150 ms), are dependent on task parameters, and produce highly variable motor outputs (e.g., reach for a nearby stable support surface or walk away from a destabilizing condition).
- *Automatic postural reactions* have intermediate latencies (80 to 120 ms) and are the first responses that effectively prevent falls. They produce quick, relatively invariant movements among individuals (similar to reflexes), but they require coordination of responses among body regions and are modifiable depending on the demands of the task (similar to voluntary responses).

The reflex, automatic, and voluntary movement systems interact to ensure that the response matches the postural challenge.

Ankle Strategy (Anteroposterior Plane)

In quiet stance and during small perturbations (i.e., slow-speed perturbations usually occurring on a large, firm surface), movements at the ankle act to restore a person's COM to a stable position. For small external perturbations that cause loss of balance in a forward direction (i.e., platform displacements in a backward direction), muscle activation usually proceeds in a distal to proximal sequence: gastrocnemius activity beginning about 90 to 100 ms after perturbation onset, followed by the hamstrings 20 to 30 ms later, and finally paraspinal muscle activation.[104,105] In response to backward instability, muscle activity begins in the anterior tibialis, followed by the quadriceps and abdominal muscles.

Weight-Shift Strategy (Lateral Plane)

The movement strategy utilized to control mediolateral perturbations involves shifting the body weight laterally from one leg to the other. The hips are the key control points of the weight-shift strategy. They move the COM in a lateral plane primarily through activation of hip abductor and adductor muscles, with some contribution from ankle invertors and evertors.[105]

Suspension Strategy

The suspension strategy is observed during balance tasks when a person quickly lowers his or her body COM by flexing

TABLE 8.1 Characteristics of the Three Movement Systems for Balance Control Following Perturbations

Characteristic	Reflex	Automatic	Voluntary
Mediating pathway	Spinal cord	Brain stem/subcortical	Cortical
Mode of activation	External stimulus	External stimulus	External stimulus or self-stimulus
Comparative latency of response	Fastest	Intermediate	Slowest
Response	Localized to point of stimulus and highly stereotyped	Coordinated among leg and trunk muscles; stereotypical but adaptable	Coordinated and highly variable
Role in balance	Muscle force regulation	Resist disturbances	Generate purposeful movements
Factors modifying the response	Musculoskeletal or neurological abnormalities	Musculoskeletal or neurological abnormalities; configuration of support; prior experience	Musculoskeletal or neurological abnormalities; conscious effort; prior experience; task complexity

Adapted from Nashner.[105]

the knees, causing associated flexion of the ankles and hips.[106] The suspension strategy can be combined with the ankle or the weight-shift strategy to enhance the effectiveness of a balance movement.[106]

Hip Strategy

For rapid and/or large external perturbations or for movements executed with the COG near the limits of stability, a hip strategy is employed.[106] The hip strategy uses rapid hip flexion or extension to move the COM within the BOS.[162] As the trunk rotates rapidly in one direction, horizontal (shear) forces are generated against the support surface in the opposite direction moving the COM in the opposite direction as the trunk.[106] The muscle activity associated with the hip strategy has been studied by having a person stand crosswise on a narrow balance beam while the support surface suddenly moves backward (i.e., person sways forward) or forward (i.e., person sways backward).[61] In response to a forward body sway, muscles are typically activated in a proximal to distal sequence: Abdominals beginning about 90 to 100 ms after perturbation onset followed by activation of the quadriceps. Backward body sway results in activation first of the paraspinals followed by the hamstrings. A person cannot use the hip strategy to restore balance while walking on slippery surfaces, because the large horizontal forces generated cause the feet to slip.

Stepping Strategy

If a large force displaces the COM beyond the limits of stability, a forward or backward step is used to enlarge the BOS and regain balance control. The uncoordinated step that follows a stumble on uneven ground is an example of a stepping strategy.

Combined Strategies

Research has shown that movement response patterns to postural perturbations are more complex and variable than originally described by Nashner.[75] Most healthy individuals use combinations of strategies to maintain balance depending on the control demands. Balance control requirements vary depending on the task and the environment. For example, standing on a bus that is moving has higher control demands than standing on a fixed surface. Therefore, it is important during treatment of balance disorders to vary the task and environment, so the person develops movement strategies for different situations.

Balance Control Under Varying Conditions

Balance During Stance

In quiet stance, the body sways like an inverted pendulum about the ankle joint.[162] The balance goal is to keep the body's COM safely within the BOS. To accomplish this goal, an ankle strategy is utilized in which ankle muscles (i.e., ankle plantarflexors/dorsiflexors, invertors/evertors) are automatically and selectively activated to counteract body sway in different directions. Other muscles that are tonically active during quiet stance to maintain an erect posture are the gluteus medius and tensor fasciae latae, the iliopsoas to prevent hyperextension of the hip, and the thoracic paraspinals (with some intermittent abdominal activation).[9] Body alignment contributes to stability in quiet stance. Standing with the body in optimal body alignment allows the body to maintain balance with the least amount of muscle energy expenditure.[137]

Balance with Perturbed Standing

Perturbations to balance in standing can be either internal (i.e., voluntary movement of the body) or external (i.e., forces applied to the body). Both types of perturbations involve activation of muscle synergies, but the response timing is proactive (i.e., anticipatory) for internally generated perturbations and reactive for externally generated perturbations.[162]

Moving platform experiments have provided much information about the motor strategies (i.e., ankle, hip, and stepping strategies) and associated muscle activation patterns that result when a person is standing on a surface that unexpectedly translates or tilts.[76,102,104,106] With repetition of a platform perturbation, learning adaptation occurs that is characterized by a significant reduction in the reactive response.[91,102] For example, Nashner[102] found that upward rotation of a platform initially elicited reflex contractions of the gastrocnemius muscles of subjects, giving them the false impression that their bodies were falling forward; with repeated tilts, the gastrocnemius response diminished, and by the fourth repetition, it was completely absent. Thus, prior experience and feedforward anticipatory control have an important influence on balance responses.

Balance During Whole-Body Lifting

One of the most common ways that balance is challenged during everyday life is when lifting boxes or other large objects that are resting on the floor or at a level that is low relative to the person's COM (Fig. 8.4). Loss of balance during lifting may result in a fall, slip, or back injury.[6,121,132]

COM shift. During lifting, the movement of the body toward the load disturbs the position of the COM. When a load is lifted in front of the body, the COM is shifted forward during flexion of the trunk and legs, which is an internal disturbance to balance. The COM is further displaced forward when the load is added to the hands, creating an external disturbance to balance. In this case, anticipatory postural adjustments are needed to match whole-body backward momentum (horizontal linear and angular) to the displacement of the body and magnitude of the expected load.[29,53,54] The CNS estimates the amount of momentum necessary for lifting the load based on previous experience with the load or other objects of similar physical properties (e.g., size, weight, and density).[54] The generation of backward horizontal linear momentum serves to keep the COM of the body within the base of support. The generation of angular momentum is essential for movement of the person with the load toward the upright posture.

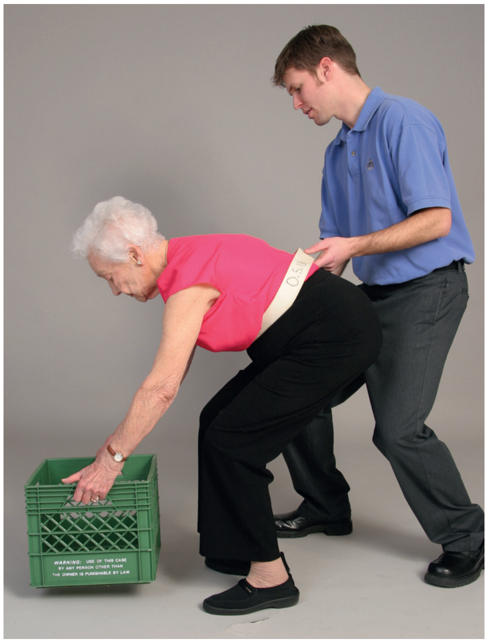

FIGURE 8.4 Balance during forward lifting with knees flexed.

Anticipated weight and momentum. The amount of whole-body momentum and the lifting force generated are scaled to the anticipated weight of the load.[54] When a heavy load is expected, sufficient levels of backward horizontal and angular momentum are needed to counteract the additional load, which tends to pull and rotate the body COM forward. Subtle differences in lifting posture, which reflect the underlying differences in momentum, occur when subjects lift a light load versus a heavy load (Fig. 8.5). Subjects tend to flex their hips and knees more and shift their weight back when lifting a heavy load (dark circles) than when lifting a light load (light circles).

Loss of balance. Loss of balance during lifting can occur when subjects overestimate or underestimate the weight of the load.[53] When the load weight is overestimated, too much momentum is generated and the body tends to topple backward. Most subjects compensate for this loss of balance by taking a step backward. When the load weight is underestimated, too little momentum is generated and the body tends to topple forward, resulting in the load quickly coming back to the ground.

Lifting style. The lifting style does appear to affect the challenges to balance. Keeping the knees more extended during lifting (Fig. 8.6) reduces the risk of balance loss, especially when the quadriceps are weak. Research comparing lifting styles has found that loss of balance was more common when subjects used a style of lifting in which the knees were more flexed compared to when the knees were straighter.[26,28,53,147]

Lifting instructions. Clinicians frequently instruct patients to use the leg lifting style, with the knees bent and the trunk erect, when lifting loads (Fig. 8.7).[97,140] This recommendation is based on the assumption that leg lifting imposes lower compression loads on the spine than other styles of lifting, such as the stoop lift, with the knees straight and the trunk flexed.[82] This assumption is likely true when the load to be lifted can be placed between the feet (Figs. 8.7 and 8.8). However, van Dieen and colleagues[153] found little evidence in the biomechanical literature to support that leg lifting generally results in lower loads on the spine than back lifting. Recent research, using sophisticated biomechanical models, indicates that leg lifting results in higher compression forces on the spine compared to back lifting when the load is not positioned between the legs.[23,34,77,119] Although researchers have consistently found that bending moments and fascial strain are substantially greater with the back lift compared to the squat lift,[34,35] the magnitude of the bending moments on the spine appear to be well below the threshold for injury.[1,34,152]

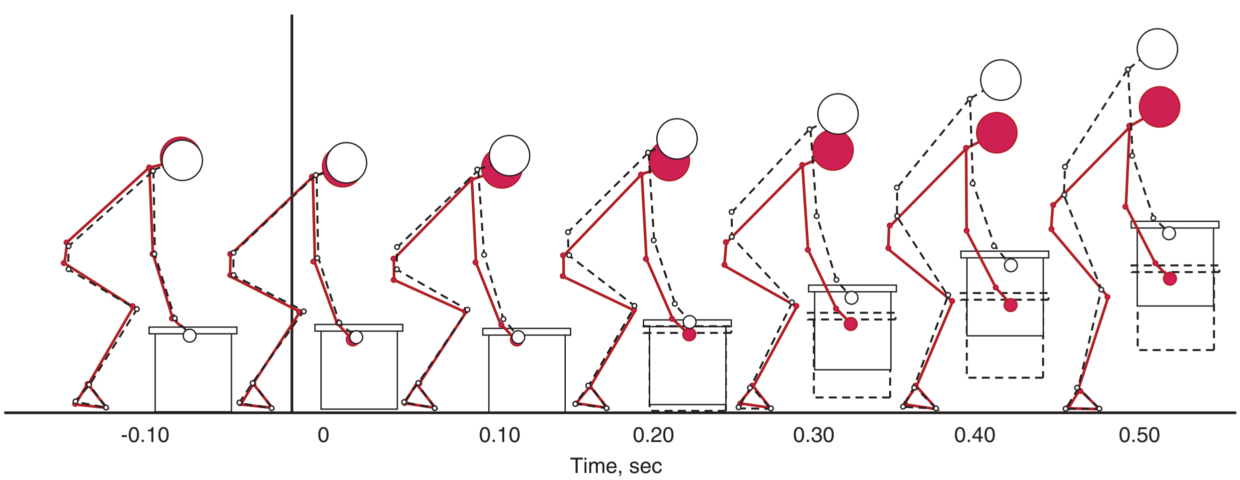

FIGURE 8.5 Postural adjustments for lifting a heavy versus a light load. When subjects approach a load (indicated by the vertical bar at time 0), early in the lift subtle differences in the anticipatory postural adjustments are evident. When a heavy load is expected (dark circles) there is greater flexion of the trunk, hips, and knees compared to when a light load is expected (light circles). *(Adapted from Heiss et al[54])*

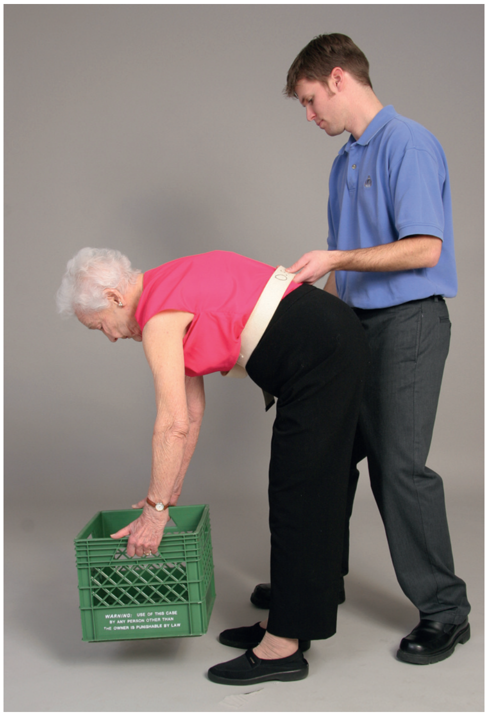

FIGURE 8.6 Balance during forward lifting with knees extended.

FIGURE 8.7 Squat lift with trunk erect and object placed between the feet.

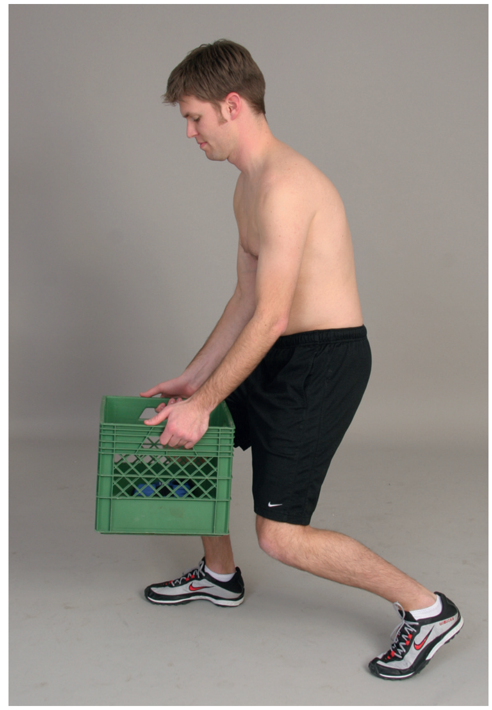

FIGURE 8.8 Straddle lift with trunk erect and object placed between the feet.

Lifting styles. Based on the current literature, it appears that if the objective of training for lifting is to reduce the load on the lumbar spine, other factors that have a more substantial effect on reducing the load on the lumbar spine should be emphasized over the selection of a lifting style, especially when placing the load between the legs is not feasible.

CLINICAL TIP

Important factors for safe lifting include maintaining a neutral spine, slowing the lifting speed, optimizing the horizontal and vertical position of the load, avoiding asymmetrical lifts (because of the increased lateral and twisting moments on the spine) (Fig. 8.9), and reducing the load weight.[152]

If maintaining balance is a concern—especially in the elderly—lifting styles in which the knees are more extended, such as with the semi-squat and stoop lift, are probably safer. In younger individuals with strong quadriceps, the straddle lift with one leg in front of the other to widen the base of support would reduce the risk of balance loss.

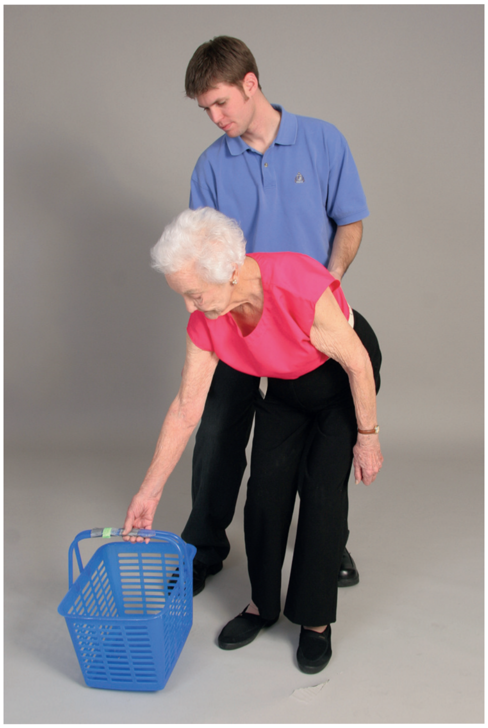

FIGURE 8.9 Side lift with the right trunk in lateral flexion and rotation results in high loads on the lumbar spine and should be avoided.

Balance in Unperturbed Human Gait

During walking, the COM is always outside the BOS except during the short double support period.[162] Therefore, the balance goal is to move the body outside the BOS by letting the body fall forward and yet prevent a fall. To accomplish this goal, a person must be able to maintain balance and posture of the upper body (i.e., head, arms, trunk) and vertical alignment of the body against gravity. Trunk and hip muscles (flexors/extensors in the sagittal plane; abductors/adductors in the frontal plane) keep the upper body balanced, and extensor muscles of the lower extremities prevent vertical collapse.[162,163] The ankle muscles control anterior/posterior or medial/lateral acceleration of the body's COG but are not able to prevent falls.[162] Fine motor control of the foot during the swing phase involving anticipatory activation of the ankle dorsiflexors ensures minimum toe clearance (0.55 cm) to prevent trips.[117]

Impaired Balance

Impaired balance can be caused by injury or disease to any structures involved in the three stages of information processing—sensory input, sensorimotor integration, and motor output generation.

Sensory Input Impairments

Proprioceptive deficits have been implicated as contributing to balance impairments following lower extremity and trunk injuries or pathologies. Decreased joint position sense has been reported in individuals with recurrent ankle sprains,[13,43,45,49] knee ligamentous injuries,[8,116,128] degenerative joint disease,[8] and low back pain.[16,47,81] These same conditions have been associated with increased postural sway compared to that of controls.[3,19,31,43,45,81,98,159] It is unclear whether decreased joint position sense is due to changes in joint receptors or in muscle receptors.

Somatosensory, visual, or vestibular deficits may impair balance and mobility.

- Reduced somatosensation in the lower extremities caused by peripheral polyneuropathies in the aged and in individuals with diabetes are associated with balance deficits[123,124,138,151] and an increased risk for falls.[68,124] These individuals tend to rely more heavily on a hip strategy to maintain balance than do those without somatosensory deficits.[62]
- Visual loss or specific deficits in acuity, contrast sensitivity, peripheral field vision, and depth perception caused by disease, trauma, or aging can impair balance and lead to falls.[25,71]
- Individuals with damage to the vestibular system due to viral infections, traumatic brain injury (TBI), or aging may experience vertigo (a feeling of spinning) and postural instability. Black and colleagues[11] found that patients with severe bilateral loss of vestibular function are unable to use hip strategies even when standing crosswise on a narrow beam, although ankle strategies are unaffected.

Sensorimotor Integration Impairments

Damage to the basal ganglia, cerebellum, or supplementary motor area impair processing of incoming sensory information, resulting in difficulty adapting sensory information in response to environmental changes and in disruption of anticipatory and reactive postural adjustments.[63,105,137] When stance is perturbed by platform translations, patients with Parkinson's disease tend to have a smaller than normal amplitude of movement due to co-activation of muscles on both sides of the body, whereas patients with cerebellar lesions typically demonstrate larger response amplitudes.[137]

Sensory organization problems that manifest as overreliance on one particular sense for balance control or a more generalized inability to select an appropriate sense for balance control when one or more senses give inaccurate information have been demonstrated in patients with a wide variety of neurological conditions.[137] Individuals who rely heavily on visual inputs (visually dependent) or somatosensory inputs (surface dependent) become unstable or fall under conditions in which the preferred sense is either absent or inaccurate, whereas those with generalized adaptation problems are unstable in any condition in which a sensory input is not accurate.

Biomechanical and Motor Output Impairments

Deficits in the motor components of balance control can be caused by musculoskeletal (i.e., poor posture, joint ROM limitations, decreased muscle performance) and/or neuromuscular system (i.e., impaired motor coordination, pain) impairments. Postural malalignment, such as the typical thoracic kyphosis of the elderly, that shifts the COM away from the center of the BOS increases a person's chance of exceeding his or her limits of stability.[105] Because each segment within the legs exerts forces on its adjunct segments, impaired ROM or muscle strength at one joint can alter posture and balance movements throughout the entire limb. For example, restriction of ankle motion by contractures or wearing ankle-foot orthoses and/or ankle dorsiflexor weakness eliminates the use of an ankle strategy, resulting in increased use of hip and trunk muscles for balance control.[18,130]

In individuals with neurological conditions (e.g., stroke, TBI, Parkinson's disease), failure to generate adequate muscle forces due to abnormal tone or impaired coordination of motor strategies may limit the person's ability to recruit muscles required for balance.[137]

Pain can alter movements, reduce a person's normal stability limits, and, if persistent, produce secondary strength and mobility impairments.

Deficits with Aging

Falls are common and are a major cause of morbidity, mortality, reduced functioning, and premature nursing home admissions in persons over age 65.[25,36,109,127,129] The most common risk factors associated with falls in the elderly are listed in Box 8.2. Most falls by the elderly are likely due to complex interactions between multiple risk factors. Clinicians are encouraged to follow published guidelines for the prevention of falls by older persons when prescribing fall prevention interventions.[4]

BOX 8.2 Most Common Risk Factors for Falls Among the Elderly

- Muscle weakness
- History of falls
- Gait deficit
- Balance deficit
- Use of assistive device
- Visual deficit
- Arthritis
- Impaired activities of daily living
- Depression
- Cognitive impairment
- Age >80 years

From AGS Panel on Fall Prevention, 2001.

Declines in all sensory systems (somatosensory, vision, vestibular) and all three stages of information processing (i.e., sensory processing, sensorimotor integration, motor output) are found with aging.[83,137] In comparison to young adults, older adults have more difficulty maintaining balance when sensory inputs from more than one system are greatly reduced, particularly when they must rely solely on vestibular inputs for balance control.[124,165] Studies of response patterns to platform perturbations in older adults have demonstrated the following motor strategy changes compared to those of young adults.

- Slower-onset latencies[139,165]
- More frequent use of a hip strategy for balance control[64]
- Limitations in the ability to maintain balance when challenged with perturbations of increasing magnitude and velocity[84]

Impaired anticipatory postural adjustments prior to making voluntary movements have been demonstrated in older individuals and may explain the high incidence of falls during activities such as walking, lifting, and carrying objects.[42,70] Valid and reliable outcome measures for assessing fall risk in the elderly are listed in Table 8.2.

CLINICAL TIP

Divided attention as when a person is doing two tasks simultaneously (i.e., walking while doing a secondary cognitive or motor task) can lead to postural instability and falls, particularly in the elderly.[122,136] Modified versions of the Timed Up-and-Go Test[118] with secondary cognitive and motor tasks can be used by clinicians to assess the influence of divided attention on balance control.[89,134] If deficits are found, patients should be allowed to practice walking while doing a secondary task and progress to doing multiple tasks according to their improvements in performance.

Elderly individuals who have experienced one or more falls may develop fear of falling, which leads to a loss of confidence in a person's ability to perform routine tasks, restricted activity, social isolation, functional decline, depression, and decreased quality of life.[25,79] The fear of falling arises more often from a person's fear of institutionalization than a fear of injury.[67] Individuals with fear of falling demonstrate perceived stability limits that are reduced from their actual stability limits and gait changes, including decreased stride length, reduced speed, increased stride width, and increased double-support time.[24,90] It is important that clinicians screen patients for fear of falling with instruments, such as the Activities-Specific Balance Confidence (ABC) Scale[120] or the Fall Efficacy Scale,[145] so evidence-based interventions that reduce fear of falling and promote physical, social, and functional activity are implemented.[15,141,156]

TABLE 8.2 Outcome Measures for Fall Risk Assessment

Outcome Measure	*Perfect Score*	*Cut-off Score (Sensitivity, Specificity)**
Berg Balance Test	56	<46 (25%, 87% for predicting any fall and 42%, 87% for multiple falls)[100]
Tinetti Performance-Oriented Mobility Assessment	28 (Balance subscale 16, Gait subscale 12)	<19/28[146]; <14/16 (68%, 78%)** balance subscale only
Timed Up-and-Go Test	N/A (timed test)	>13 seconds (87%, 87%)[134]
Four-Square Step Test	N/A (timed test)	>15 seconds (85%, 88%)[33]
Dynamic Gait Index	24	<20 (59%, 64%)[133]
Functional Gait Assessment	30	<22 (100%, 72%)[166]
Five-Times-Sit-to-Stand Test	N/A (timed test)	15 seconds (55%, 65%)[17]
ABC Scale	100%	<67%[80]

*Sensitivity and specificity values are given for community-dwelling elderly. **Sensitivity and specificity values are for elderly in residential care facilities.

Deficits from Medications

There is an increased risk of falling among older individuals who take four or more medications and among those taking certain medications (i.e., hypnotics, sedatives, tricyclic antidepressants, tranquilizers, antihypertensive drugs) due to dizziness or other side effects.[4,25] Individuals who have fallen should have their medications reviewed and altered or stopped as appropriate to prevent future falls.

Management of Impaired Balance

Examination and Evaluation of Impaired Balance

The key elements of a comprehensive evaluation of individuals with balance problems include the following.

- A thorough history of falls (whether onset of falls is sudden versus gradual; the frequency and direction of falls; the environmental conditions, activities, and presence of dizziness, vertigo, or lightheadedness at time of the fall; current and past medications; presence of fear of falling)
- Assessments to identify sensory input (proprioceptive, visual, vestibular), sensory processing (sensorimotor integration, anticipatory and reactive balance control), and biomechanical and motor (postural alignment, muscle strength and endurance, joint ROM and flexibility, motor coordination, pain) impairments contributing to balance deficits
- Tests and observations to determine the impact of balance control system deficits on functional performance
- Environmental assessments to determine fall risk hazards in a person's home.[25]

Commonly used tests and measures for each of the three categories of balance assessment described in the *Guide to Physical Therapist Practice*[5] are presented in Table 8.3. Clinicians should carefully select a variety of tests and measures that assess all of the various types of balance control.

Static Balance Tests

Static balance can be assessed by observing the patient's ability to maintain different postures.

- The Romberg Test[110] tests the patient's ability to stand with the feet parallel and together with the eyes open and then closed for 30 seconds..
- The sharpened Romberg, also known as the tandem Romberg,[110] requires the patient to stand with the feet in a heel-to-toe position with arms folded across the chest and eyes closed for one minute.
- The Single-Leg Balance Stance Test[154] (SLB) asks the patient to stand on one leg without shoes with arms placed across the chest without letting the legs touch each other. Five 30-second trials are performed for each leg, with a maximum possible score of 150 seconds per leg. The SLB is reliable and has been found to predict injurious falls in community-dwelling elderly[154] and ankle sprains in athletes.[148]
- The Stork Stand Test[74] is performed by having the patient stand on both feet with hands on the hips, then lift one leg and place the toes of that foot against the knee of the other leg. On command from the tester, the patient then raises the heel to stand on the toes and tries to balance for as long as possible without letting either the heel touch the ground or the other foot move away from the knee. Normal adults should be able to balance for 20 to 30 seconds on each leg.

TABLE 8.3 Balance Assessments and Interventions

Category of Assessment	Clinical Tests/Measures	Interventions if Deficits Present
I. Balance*		
Static	Observations of patient maintaining different postures; Romberg Test[110]; sharpened (tandem) Romberg[110]; Single-Leg Stance Test[154] Stork Stand Test [74]	Vary postures Vary support surface Incorporate external loads
Dynamic	Observations of patient standing or sitting on unstable surface or performing postural transitions and functional activities; Five-times-sit-to-stand Test (5 × STS)[32]	Moving support surfaces Move head, trunk, arms, legs Transitional and locomotor activities
Anticipatory (feedforward)	Observations of patient catching ball, opening doors, lifting objects of different weights; Functional Reach Test[37]; Multidirectional Reach Test[111]; Star Excursion Balance Test[114]	Reaching Catching Kicking Lifting Obstacle course
Reactive (feedback)	Observation of patient's responses to pushes (small or large, slow or rapid, anticipated and unanticipated); Pull Test[101]; Push and release Test (PRT)[72]; Postural Stress Test[164]	Standing sway Ankle strategy Hip strategy Stepping strategy Perturbations
Sensory organization	Clinical Test of Sensory Integration on Balance Test (CTSIB) also called the "Foam and Dome" Test[135]	Reduce visual inputs Reduce somatosensory cues
II. Balance during functional activities*	Tinetti Performance-Oriented Mobility Assessment (POMA)[144]; Timed Up and Go Test (TUG)[118]; Berg Balance Scale (BBS)[10]; Four Square Step Test (4SST)[33]; Dynamic Gait Index (DGI)[137]; Functional Gait Assessment (FGA)[167]; Community Balance and Mobility Scale[65]; High Level Mobility Assessment (HiMat)[160]; Dizziness Handicap Inventory (DHI)[73]	Functional activities Dual or multitask activities (e.g., walking with secondary cognitive or motor task)
III. Safety during gait, locomotion, or balance*	Observations; home assessments; Activities-Specific Balance Confidence (ABC) Scale [120]; Falls Efficacy Scale[145]	Balance within stability limits; environmental modifications; assistive devices; external support

*With or without the use of assistive, adaptive, orthotic, protective, supportive, or prosthetic devices or equipment.[5]

Dynamic Balance Tests

Dynamic balance control can be assessed by observations of how well the patient is able to stand or sit on unstable surfaces (e.g., foam or Swiss ball), transition from one position to another (e.g., supine-to-sit or sit-to-stand transfers), and perform activities such as walking, jumping, hopping, and skipping.

- The Five-times-sit-to-stand test (5× STS) can be used to evaluate balance control when moving between sitting and standing.[32] The person is seated in a chair with the arms across the chest and then stands up and sits back down as quickly as possible five times consecutively while being timed. A score of >15 seconds on the 5× STS was found to predict recurrent falls (sensitivity 55%, specificity 65%) in 2,735 community-dwelling elderly individuals.[17]

Anticipatory Postural Control Tests

Anticipatory postural control is evaluated by having the patient perform voluntary movements that require the development of a postural set to counteract a predicted postural disturbance. The patient's ability to catch balls, open doors, lift objects of different weights, and reach without losing balance is indicative of adequate anticipatory control.

- The Functional Reach Test[37] and the Multi-Directional Reach Test[111] require the patient to reach in different directions as far as possible without changing the BOS. Normative data are available, and the tests are reliable and valid.[111]
- The Star Excursion Balance Test is a test of lower extremity reach that challenges an individual's limits of stability.[114] The patient is instructed to reach as far as possible with one

leg in each of eight prescribed directions while maintaining balance on the contralateral leg. The test is reliable[56,78] and can detect deficits in individuals with chronic ankle instability.[57,114]

Reactive Postural Control Tests

Automatic postural responses or reactive control can be assessed by the patient's response to external perturbations.

- Pushes (small or large, slow or rapid, anticipated and unanticipated) applied in different directions to the sternum, posterior trunk, or pelvis are used widely, but they are not quantifiable or reliable. The clinician subjectively rates the responses as normal, good, fair, poor, or unable.
- The Pull Test,[101] Push and Release Test,[72] and Postural Stress Test[164] are more objective and reliable measures of reactive postural control.

Sensory Organization Tests

The Clinical Test of Sensory Integration on Balance Test (CTSIB), also called the "Foam and Dome" Test,[135] measures the patient's ability to balance under six different sensory conditions.

1. Standing on a firm surface with the eyes open (visual, somatosensory, and vestibular information accurate);
2. Standing on a firm surface with the eyes closed (somatosensory and vestibular information accurate);
3. Standing on a firm surface wearing a dome made from a modified Japanese lantern (somatosensory and vestibular information accurate, visual information inaccurate);
4. Standing on a foam cushion with the eyes open (visual and vestibular information accurate, somatosensory inaccurate);
5. Standing on foam with the eyes closed (vestibular information accurate, somatosensory information inaccurate); and
6. Standing on foam wearing the dome (vestibular information accurate, somatosensory and visual information inaccurate).

The patient stands with feet parallel and arms at sides or hands on hips. A minimum of three 30-second trials of each condition are performed.

- Individuals who rely heavily on visual inputs for balance (i.e., visual dependent) will become unstable or fall in conditions 2, 3, 5, and 6.
- Those who rely heavily on somatosensory inputs (i.e., surface dependent) show deficits with conditions 4, 5, and 6.
- With generalized adaptation problems, individuals are unstable in conditions 3, 4, 5, and 6.
- Individuals with vestibular loss are very unstable in conditions 5 and 6.

NOTE: A computerized version of the CTSIB using a moveable force plate and visual surround is called the Sensory Organization Test (SOT).[105]

Functional Tests

Functional tests are used to determine activity limitations and participation restrictions and to identify tasks that a patient needs to practice. Three mobility scales (i.e., Tinetti Performance-Oriented Mobility Assessment [POMA],[144] Timed Up and Go Test [TUG],[118] Berg Balance Scale,[10] Four Square Step Test [4SST[33]]), and two gait scales (i.e., Dynamic Gait Index[137] and Functional Gait Assessment[167]) can be easily used to assess balance performance during functional activities. Most of these tests were designed to assess fall risk in the elderly, with the exception of the Functional Gait Assessment, which was developed specifically for use with patients with vestibular disorders. The Community Balance and Mobility Scale[65] and the High Level Mobility Assessment Tool (HiMAT)[160] can be used to evaluate balance and mobility in people who are ambulatory and functioning at a high level, yet have some balance deficits. The 25-item Dizziness Handicap Scale is a questionnaire that can evaluate the self-perceived impact of dizziness and unsteadiness on functional activities in people with vestibular disorders.[73]

Balance Training

There are many factors to consider when developing an intervention program for balance impairments. Most balance intervention programs require a multisystem approach. For example, an individual who has experienced prolonged bed rest or inactivity following an illness may require a program that includes stretching the lower extremities and trunk to improve postural alignment and mobility; strengthening exercises to improve motor performance; and dynamic, functional balance activities to improve the ability to perform daily activities safely. The following elaborates on the interventions suggested previously (see Table 8.3), which are based on identified deficits in static, dynamic, anticipatory, and reactive control as well as problems involving sensory organization, function, and safety. For specific procedures to address musculoskeletal problems such as strength, joint mobility, flexibility, or posture, refer to the chapters addressing these interventions or to chapters focused on specific regions of the body.

Because balance training often involves activities that challenge the patient's limits of stability, it is important that the therapist takes steps to ensure the patient's safety. Box 8.3 lists safety measures that should be considered and utilized to prevent falls and injuries during therapy.

CLINICAL TIP

Cognitive deficits can considerably impact the success of balance training programs. If deficits are moderate to severe and a person is unable to follow directions, then performance of specific balance exercises may be unsafe and have limited success. In these cases, repetitive practice of common functional activities is advised.

BOX 8.3 Safety During Balance Training

1. Use a gait belt any time the patient practices exercises or activities that challenge or destabilize balance.
2. Stand slightly behind and to the side of the patient with one arm holding or near the gait belt and the other arm on or near the top of the shoulder (on the trunk, not the arm).
3. Perform exercises near a railing or in parallel bars to allow patient to grab when necessary.
4. Do not perform exercises near sharp edges of equipment or objects.
5. Have one person in front and one behind when working with patients at high risk of falling or during activities that pose a high risk of injury.
6. Check equipment to ensure that it is operating correctly.
7. Guard patient when getting on and off equipment (such as treadmills and stationary bikes).
8. Ensure that the floor is clean and free of debris.

Static Balance Control

Activities to promote static balance control include having the patient maintain sitting, half-kneeling, tall kneeling, and standing postures on a firm surface.

- More challenging activities include practice in the tandem and single-leg stance (Fig. 8.10), lunge, and squat positions.
- Progress these activities by working on soft surfaces (e.g., foam, sand, grass), narrowing the base of support, moving the arms, or closing the eyes.
- Provide resistance via handheld weights or elastic resistance (Figs. 8.11 and 8.12).
- Add a secondary task (i.e., catching a ball or mental calculations) to further increase the level of difficulty (Fig. 8.13).

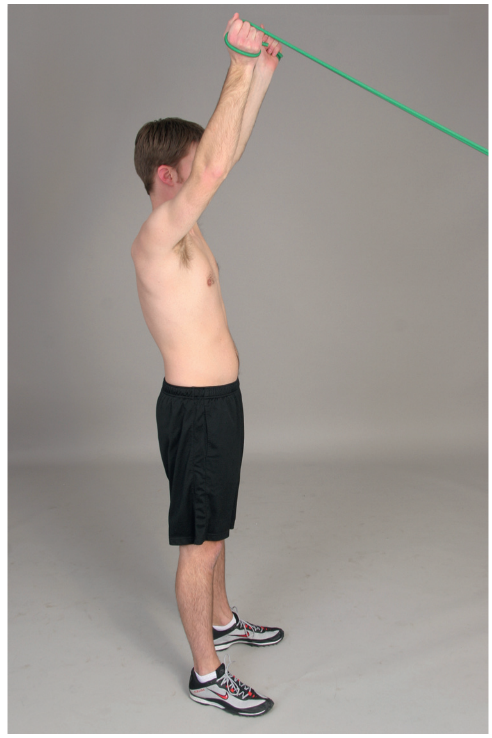

FIGURE 8.11 Balance while standing with resistance provided to the arms via elastic resistance.

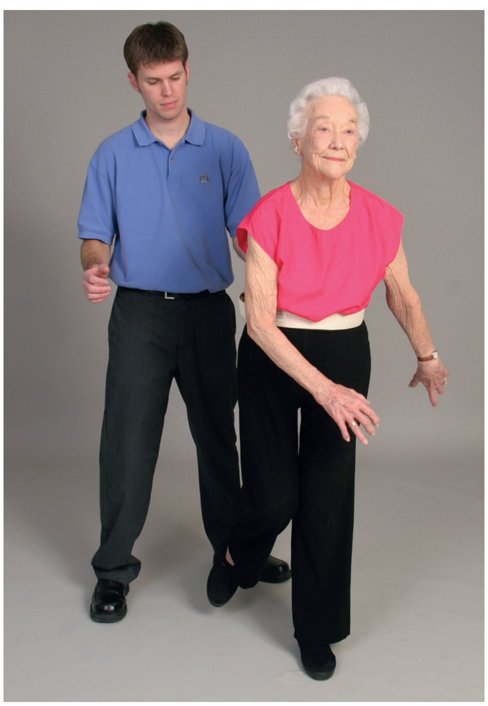

FIGURE 8.10 Balance during single leg stance.

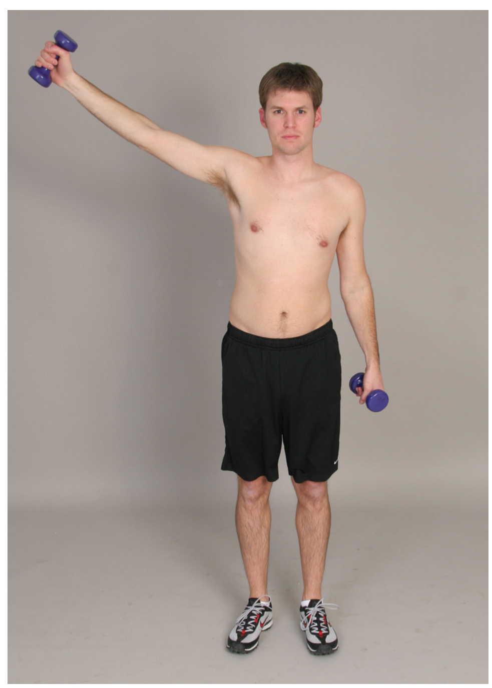

FIGURE 8.12 Balance while standing with arm abducting and holding a weight.

FIGURE 8.13 Balance while standing and catching a ball.

FIGURE 8.14 Balance while standing on wobble boards.

Dynamic Balance Control

To promote dynamic balance control, interventions may involve the following.

- Have the patient maintain equal weight distribution and upright trunk postural alignment while on moving surfaces, such as sitting on a therapeutic ball, standing on wobble boards (Fig. 8.14), or bouncing on a mini-trampoline.
- Progress the activities by superimposing movements such as shifting the body weight, rotating the trunk, moving the head or arms (Fig. 8.15).
- Vary the position of the arms from out to the side to above the head (Fig. 8.16).
- Practice stepping exercises starting with small steps, then mini-lunges to full lunges.
- Progress the exercise program to include hopping, skipping, rope jumping, and hopping down from a small stool while maintaining balance.
- Have the patient perform arm and leg exercises while standing with normal stance, tandem stance, and single-leg stance (Fig. 8.17).

FIGURE 8.15 Balance while standing on wobble boards with arm movements.

FIGURE 8.16 Balance while standing on wobble boards with arms above the head.

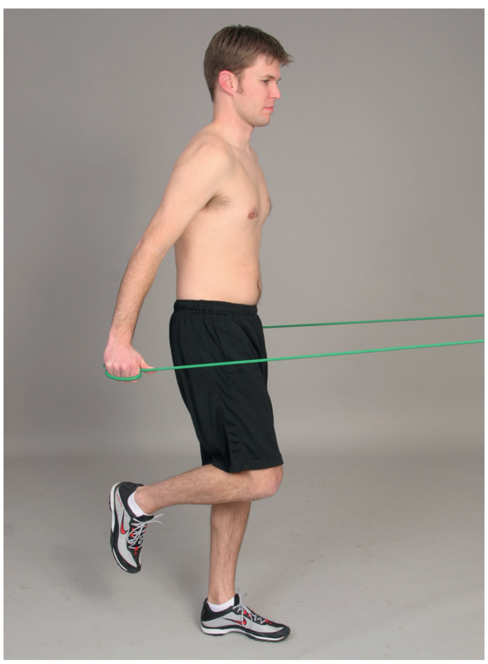

FIGURE 8.17 One-legged stance with resisted shoulder extension using elastic resistance.

Anticipatory Balance Control

Practice anticipatory balance control by performing the following.

- Reach in all directions to touch or grasp objects, catching a ball, or kicking a ball.
- Use different postures for variation (e.g., sitting, standing, kneeling) and throwing or rolling the ball at different speeds and heights (Fig. 8.18).
- Use functional tasks that involve multiple parts of the body to increase the challenge to anticipatory postural control by having the patient lift objects of varying weight in different postures at varying speeds, open and close doors with different handles and heaviness, or maneuver through an obstacle course.

FIGURE 8.18 Balance when standing while reaching and catching the ball overhead.

Reactive Balance Control

Train reactive balance control by using the following activities.

- Have the patient work to gradually increase the amount of sway when standing in different directions while on a firm stable surface.
- To emphasize training of the *ankle strategy*, have the patient practice while standing on one leg with the trunk erect.
- To emphasize training of the *hip strategy*, have the patient walk on balance beams or lines drawn on the floor; perform tandem stance and single-leg stance with trunk bending; or stand on a mini-trampoline, rocker balance, or sliding board.
- To emphasize the *stepping strategy*, have the patient practice stepping up onto a stool or stepping with legs crossed in front or behind other leg (e.g., weaving or braiding).

- To increase the challenge during these activities, add anticipated and unanticipated external forces. For example, have the patient lift boxes that are identical in appearance but of different weights; throw and catch balls of different weights and sizes; or while on a treadmill, suddenly stop/start the belt or increase/decrease the speed.

Sensory Organization

Many of the activities previously described can be utilized while varying the reliance on specific sensory systems.

- To reduce or destabilize the *visual inputs*, have the patient close the eyes, wear prism glasses, or move the eyes and head together during the balance activity.
- To decrease reliance on *somatosensory cues*, patients can narrow the BOS, stand on foam, or stand on an incline board.

Balance During Functional Activities

Focus on activities similar to the functional limitations identified in the evaluation. For example:

- If reaching is limited, have the patient work on activities, such as reaching for a glass in a cupboard, reaching behind (as putting arm in a sleeve), or catching a ball off center.
- Perform two or more tasks simultaneously to increase the level of task complexity.
- Practice recreational activities the patient enjoys, such as golf, to increase motivation while challenging balance control (Fig. 8.19).

FIGURE 8.19 Functional balance during a golf swing.

Safety During Gait, Locomotion, or Balance

To emphasize safety, have the patient practice postural sway activities within the person's actual stability limits and progress dynamic activities with emphasis on promoting function. If balance deficits cannot be changed, environmental modifications, assistive devices, and increased family or external support may be required to ensure safety.

CLINICAL TIP

Assistive devices, such as rollator walkers, are often appropriately prescribed as a compensatory measure for people with a variety of balance impairments. However, clinicians should be aware that assistive devices that are incorrectly fitted or used by a patient can precipitate falls. Therefore, clinicians must properly adjust and provide instruction on proper use of assistive devices to prevent unnecessary falls.

Health and Environmental Factors

In addition to exercise and balance training activities, clinicians should address several other factors affecting balance to reduce the risk of falls.[87]

Low Vision

To address low vision issues, encourage regular eye examinations with adjustments to lens prescriptions and cataract surgery, if necessary. Wearing a hat and sunglasses in bright sunlight, taking extra precautions when it is dark, and making sure lights are on when walking about the house at night are other recommendations. Advise patients to avoid using bifocal glasses when walking, because single lens glasses are safest for improving depth perception and contrast sensitivity, especially on stairs.[86]

Sensory Loss

For individuals with sensory loss in the legs, caution them to take extra care when walking on soft carpet or uneven ground and use a cane or other device if necessary. Recommend that they wear firm rubber shoes with low heels. Regular medical examinations should be encouraged to ensure that a patient's blood glucose levels and other factors (i.e., cholesterol, lipids) are under control to minimize damage to sensory nerves from diseases such as diabetes and peripheral vascular disease. Advise patients to seek medical attention if they experience any symptoms of dizziness.

Medications

Patients should be educated about the influence of certain medications, such as sedatives and antidepressants, on their risk of falling. For example, if such medications are used at night as a sleep aid, an individual should take extra precautions when getting up to use the bathroom.

Evidence-Based Balance Exercise Programs for Fall Prevention in the Elderly

Mounting evidence from randomized clinical trials indicates that therapeutic exercise is an effective tool in the prevention of falls, especially if it is incorporated with a comprehensive strategy targeting health, environmental, and behavioral risk factors that contribute to falls.[48,96] The selection of exercises and activities for balance training should be based on two major factors: the person's fall risk and the setting in which the training will take place. Economic and transportation factors also play a role in these decisions. Since people can fall while participating in balance training and exercise programs, it is critical that adequate protections are in place to prevent falls. Based on these issues, the following guidelines are proposed.

- Elderly individuals who have no history of falls and do not have scores that are within the "at risk" category on standardized balance tests should participate in an individual or community-based group exercise program incorporating muscle strengthening, balance, and coordination exercises.
- Individuals who are at risk of falls, based on standardized balance tests, but have not developed a history of falls should participate in individual or group exercise programs in which there are well-trained leaders and support staff who appropriately supervise and guard the person during the activities that challenge balance.
- People who are at risk of falls and have a history of falls require an individually tailored, supervised, exercise program by a physical therapist or physical therapist assistant and, if appropriate, a caregiver who is trained to supervise and guard the person during the home exercise activities. This program may take place in a clinic- or home-based setting.

CLINICAL TIP

According to current best evidence, an exercise program to reduce risk of falls should include at least 50 hours devoted to exercises and activities to improve balance.[131] This might be in the form of a 1-hour group exercise program twice a week for 26 weeks. A more intensive program may consist of 1-hour of balance training three times a week that is supplemented with a 30-minute daily home exercise program for 8 to 10 weeks. Although walking has many health benefits, the time devoted to a walking exercise program should be *in addition* to time spent in balance training and not a substitute for it.

Home Exercise Program for Reducing Risk of Falls for People at High Risk

The home setting may be the best option for an exercise-based falls prevention program for some people who are at high risk of falls. Reasons why the home may be the best location for such a programs include: 1) the person functions most often in this environment, therefore, the training takes place in the location where falls are most likely to occur; and 2) the person may participate more fully to his or her physical capacity without the stress and fatigue that may be associated with transportation issues.

Otego Home Exercise Program

The Otego Exercise Program[21,44,125] is a cost-effective program for reducing falls for people aged 80 and over. This program consists of an individually tailored, 30-minute leg strengthening and balance training program that is performed at home at least three times per week and is complemented with a walking plan. The program is designed to be performed for 24 weeks under the supervision of physical therapists or health professionals trained by physical therapists.[44]

- The patient receives a booklet with illustrations and instructions on each exercise.
- Ankle weights are used to provide resistance during the leg strengthening exercises that target the muscles that extend and abduct the hip and flex and extend the knee.[44]
  - The amount of resistance should be based on the amount of weight that the person can lift for 8 to 10 repetitions of the exercise before fatiguing. Most people start with 1 or 2 kg (2.2 or 4.4 lb) cuff weights.
  - The goal is for the person to be able to do two sets of 10 repetitions before the amount of weight is increased.
  - The ankle dorsiflexor and plantarflexor muscles are strengthened using body weight as the resistance (Fig. 8.20 and Fig. 8.21).
  - Box 8.4 provides a list of the strengthening exercises in the Otego program.

FIGURE 8.20 Rising up on toes to strengthen plantarflexors.

FIGURE 8.21 Rocking back onto the heels while raising the toes to strengthen dorsiflexors.

- The balance training component of the Otego Exercise Program is also tailored to the individual and emphasizes dynamic exercises that are closely related to functional activities (Fig 8.22).[44] Depending on the ability of the individual, the balance exercises may be performed by holding on to a large, stable piece of furniture or a kitchen counter and progressed by performing the exercises without support (Fig 8.23). Balance training exercises are listed in Box 8.4.

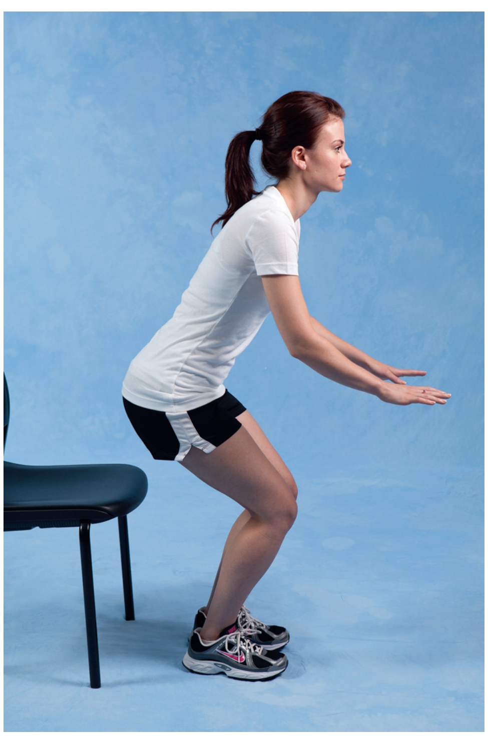

FIGURE 8.22 Practicing the sit-to-stand transfer is an important functional activity to strengthen the legs and improve dynamic balance.

- A walking program is part of the Otego Exercise Program.[44] People are told to walk for at least 30 minutes per day at their usual pace. The walking plan may be accomplished by taking walks of smaller intervals (e.g., 10 minutes) throughout the day.

FIGURE 8.23 Tandem walking **(A)** performed with light touch on a firm surface for support; and **(B)** performed without external support. Note that the therapist closely guards the patient for safety.

BOX 8.4 The Otego Home Exercise Program[44]

Lower Extremity Strengthening*

With person sitting in a hard, straight-back chair:

- Perform 5 minutes of active, gentle warm-up exercises to minimize soreness.
- Add appropriate ankle cuff weight and have patient perform unilateral knee extension.
- Repeat for the opposite leg.

With person in standing, use a counter or heavy furniture to support as needed.

- Add appropriate ankle weight and have patient perform unilateral knee flexion. Repeat for the opposite leg.
- Adjust cuff weight if necessary and have patient perform unilateral hip abduction. Repeat for the opposite leg.
- Raise up on toes to strengthen ankle plantarflexors.
- Rock back on heels for ankle dorsiflexors.

*Each exercise is to be done slowly (e.g., 2–3 seconds to lift the weight and 4–6 seconds to lower the weight) and through the full functional range of motion. The goal is to perform each exercise for two sets of 10 repetitions.

Balance Training**

- Knee bends—10 repetitions
- Backward walking—10 steps, 4 times
- Walking and turning around—Make figure of "8," 2 times
- Sideways walking—10 steps, 4 times
- Tandem stance—10 seconds
- Tandem walk—10 steps, 2 times
- Heel walking—10 steps, 4 times
- Toe walking—10 steps, 4 times
- Sit to stand—5 stands with two hands, 5 stands with one hand or 10 stands with two hands, 10 stands with one hand, 10 stands with no support, 10 stands with no support repeated

**The easiest level for the balance exercises is to use two hands for support. Progression to harder levels (to one hand support and no hands for support) depends on the ability to complete the targeted number of repetitions or amount of time using smooth, controlled movements. To progress to exercises without holding onto support, the instructor must be confident that the person can safely recover balance using lower-body strategies such as stepping.

Supervised Group Program Incorporating Strengthening, Walking, and Functional Activities

A recent systematic review of the literature concluded that multimodal exercise programs incorporating muscle strengthening, gait, balance, coordination and functional exercises led to greater beneficial effects on balance than usual exercise programs, at least in the short-term.[66] There was limited evidence for long-term effectiveness. Most exercise programs lasted 3 months and met three times per week for 1 hour.

FOCUS ON EVIDENCE

One example of a supervised group program comes from a study by Means and colleagues[96] that investigated the effects of a program designed to improve balance in community-residing elders with or without a history of falls. The program incorporated activities such as stretching, strengthening, coordination exercises, body mechanics, balance training, survival training maneuvers, and walking for endurance. The participants attended 90-minute exercise sessions three times per week in groups of six to eight. The exercises were performed under the direction of a physical therapist. Initially, participants were encouraged to exercise at a "fairly light" level (equal to 11 on the 6- to 20-point Borg perceived exertion scale[12]). After the first week, participants were encouraged to exercise at a level of intensity that was "somewhat hard" (equal to 13 on the Borg scale). The participants who attended this 6-week comprehensive exercise program showed a reduction in the time to complete an obstacle course (e.g., walking, climbing stairs, opening doors, getting up from a chair, stepping over objects) and in the number of fall and fall-related injuries for up to 6 months after participation.

Box 8.5 provides general guidelines for exercise repetitions, duration of endurance walking, and progression of a supervised group program.[96]

Multisystem Group Exercise Program Incorporating a Circuit of Activities to Address Balance Impairments and Function

Nitz and Choy[112] investigated the efficacy of a balance training program that integrated individual and group exercises targeting strength, coordination, sensory systems (vision, perception, vestibular), cognition, reaction time, and static and dynamic stability. Community-residing elderly individuals with a recent history of falls were randomly assigned to two groups. One group participated in the balance training program that addressed multisystem activities. The control group participated in a more traditional group exercise program. Participants in both groups received an educational booklet on how to prevent falls in the home and attended a 1-hour exercise session once a week for 10 weeks. The exercises were led by a physical therapist assisted by one or two students when small group activities (six participants per group) were performed.

After the intervention, both groups reported a reduction in the number of falls. The reduction in falls was greater in the group that performed the circuit training program; they also showed greater improvements in functional tests of the ability to perform activities of daily living. Although the circuit training program devised by Nitz and Choy[112] clearly

BOX 8.5 Balance Exercise Program Incorporating Strengthening, Walking, and Functional Activities[96]

Week 1
Flexibility exercises (5 repetitions, 15-second hold)
Hamstring stretch
Gluteus maximus and hip flexor stretch
Gastrocnemius and soleus stretch
Paraspinal stretch
Strengthening exercises (baseline determination of preferred elastic-band strengths for lower limb exercises—1 repetition maximum)
Lower limb muscles (elastic band: 1 set of 8–10 repetitions for each leg)
Quadriceps (sitting and straight-leg raises)
Hamstrings
Gluteus maximus
Gluteus medius
Upper limb muscles (5–10 repetitions)
Push-ups
Abdominal muscles (5 repetitions)
Curl-ups with arms behind head

Instruction in body mechanics for:
Standing
Sitting
Lying
Lifting
Reaching
Carrying
Arising from floor
Ascending/descending stairs
Baseline walking evaluation (determine maximum comfortable distance)

Week 2
Flexibility exercises (as above)
Strengthening exercises: lower limb muscles (elastic band: 1 set of 10 repetitions, each leg), upper limb muscles (10 repetitions), abdominal muscles (5–10 repetitions)
Postural exercises (10 repetitions, 10-second hold)
Head and neck
Trunk

Coordination exercises
Reciprocal leg movements (10 repetitions, eyes closed)
Bridging (10 repetitions)
Sitting/standing (5 repetitions)
Braiding exercises (2 repetitions)
Reciprocal ankle motion (10 repetitions)
Rung ladder: forward stepping (2 repetitions)

"Survival" maneuvers
Floor recovery exercises—"how to get up if you should fall"
Ascending and descending stairs safely (individual practice)
Endurance walking (begin at 75%–100% of baseline minutes walked; increase at comfortable pace)

Week 3
Flexibility exercises (5 repetitions, 20-second hold)
Strengthening exercises: lower limb (2 sets of 10 repetitions), upper limb (push-ups, 10–15 repetitions), abdominals (curl-ups, 10–15 repetitions)
Postural exercises (15 repetitions, 10-second hold)
Coordination exercises (repetitions increased)
Survival maneuvers: practice (floor recovery/stairs)
Endurance walking (0–6 minutes, comfortable pace)

Week 4
Flexibility exercises (5 repetitions, 25-second hold)
Strengthening exercises: lower limb (2–3 sets of 10 repetitions), upper limb (push-ups, 15 repetitions), abdominals (curl-ups, 15 repetitions)
Postural exercises (20 repetitions, 10-second hold)
Coordination exercises (repetitions increased)
Reciprocal legs (eyes closed)
Braiding (no holding, eyes open)
Rung ladder (forward, side, and backward stepping)
Survival maneuvers: practice (floor recovery/stairs)
Endurance walking (3–8 minutes, comfortable pace)

Week 5
Flexibility exercises (5 repetitions, 30-second hold)
Strengthening exercises: lower limb (3 sets of 10 repetitions), upper limb (push-ups, 15–20 repetitions), abdominals (curl-ups, 15–20 repetitions)
Postural exercises (25 repetitions, 10-second hold)
Coordination exercises: as above with increased repetitions, plus:
Braiding (no holding, eyes closed)
Reciprocal ankle dorsi/plantar flexion (25 repetitions)
Survival maneuvers: practice (floor recovery/stairs)
Endurance walking (6–10 minutes, comfortable pace)

Week 6
Flexibility exercises (5 repetitions, 30-second hold)
Strengthening exercises: lower limb (3 sets of 10 repetitions), upper limb (push-ups, 20 repetitions), abdominals (curl-ups, 15–20 repetitions)
Postural exercises (25 repetitions, 10-second hold)
Coordination exercises (as above with increased repetitions)
Endurance walking (8–12 minutes, comfortable pace)
Survival maneuvers: practice (floor recovery/stairs)

incorporates many important activities to address multiple systems affecting balance, the results should be interpreted with caution, because there was a small sample size and a high proportion of dropouts throughout the study.

Table 8.4 provides the details of the balance exercise program, consisting of circuit training and group activities, from the Nitz and Choy study.[112]

Tai Chi for Balance Training

Tai Chi has become a popular form of exercise for balance training. Tai Chi is a traditional Chinese exercise program consisting of a sequence of whole-body movements that are performed in a slow, relaxed manner with an emphasis on awareness of posture alignment and synchronized breathing. The four styles of Tai Chi are Yang, Sun, Chen, and Wu, and

TABLE 8.4 Circuit Training Program to Address Balance Impairments and Function[112]

Activity	Responses targeted	Progression of Activity
Sit-to-stand-to-sit	Lower limb strength Functional ability Multiple tasks	Lower the height of the chair. Add/remove upper limb assistance. Hold an item in the hands, balance a cup with/without water on a saucer/tray. Add a cognitive task to the manual task.
Stepping in all directions (forward, side, and back)	Choice step reaction time Lower limb strength and coordination	Increase speed of step. Perform stepping on a soft surface. Close eyes.
Reaching to limits of stability	Challenging limits of stability Vestibular stimulation and integration Upper and lower limb strengthening	Stick objects on a wall in the front by reaching to limits in all directions up and down while keeping feet in one position. Lunge forward to pick up objects that are shifted to a high shelf to the side and behind, progress by reaching further and increasing the weight and size of objects.
Step up and down	Lower limb strengthening and endurance Step reaction time	Step up forward, backward, and sideways over blocks of various heights; increase height, repetitions, and speed of stepping.
Ankle, hip, and upper limb balance strategy practice	Lower limb strengthening Balance strategy training	Stand in front of a wall with toe touching a line 0.5 meter from the wall. Lean back toward the wall, keeping balance and dorsiflexing the feet and using arm movement to balance while lowering toward the wall.
Sideways reach task	Mediolateral muscle strengthening in lower limbs Vestibular stimulation and integration Challenging limits of stability Multiple tasks and confounded proprioceptive input	Stand between a high and a low table positioned on either side; pick up objects from one table and transfer to other table. Move the tables farther apart and increase the weight and size of the objects to increase the challenge. Perform task while standing on an exercise mat on the floor.
Ball games	Multiple tasks Hand-eye coordination Vestibular stimulation Ballistic upper and lower limb activity	Use inflated beach balls and progress to smaller or harder balls or two or three balls at once. Add a cognitive task such as naming an animal that starts with a G, while throwing and catching or kicking the ball.
Card treasure hunt/sort into suits	Coping strategies with visual conflict Vestibular stimulation and challenge of limits of stability	Prior to the session, hide playing cards in the room such that to collect the cards the participants have to bend and look under furniture, reach up high, or detect the card from a visually confounding background. Red and black teams are possible and the team with the most cards returned to a collecting point inside 5 minutes is the winner. Add the cognitive challenge of finding/sorting cards into order according to suit.

they differ in terms of principles, forms, and function. Yang style Tai Chi is the most popular and widely practiced style today and consists of 24 forms (postures and movements).[88] Tai Chi programs for the elderly may adopt a short form of Tai Chi with only 6 to 12 forms.[88] During Tai Chi training, participants learn to control the displacement of the body COM while standing and increase their lower extremity strength and flexibility during the regimens of physical movement.[27]

Some of the characteristics of Tai Chi exercise and the therapeutic rationale for why Tai Chi may affect posture and balance include the following.[157]

- The slow, continuous, even rhythm of the movements facilitates sensorimotor integration and awareness of the external environment (see Fig. 8.2).
- The emphasis on maintaining a vertical posture enhances postural alignment and perception of orientation.
- The continuous weight shifting from one leg to the other facilitates anticipatory balance control, motor coordination, and lower-extremity strength.
- Finally, the large dynamic, flowing, and circular movements of the extremities promote joint ROM and flexibility (Fig 8.24). These characteristics should be considered when recommending Tai Chi classes to patients to ensure that instructors are following these principles and that the patients are appropriate for these activities.

FIGURE 8.24 In this Tai Chi form, the participant shifts the body-weight toward one leg while moving the arms.

FOCUS ON EVIDENCE

The effectiveness of Tai Chi training depends on the duration of the program, which may range from 4 weeks to 1 year, and the targeted populations. Studies have shown that Tai Chi improves standing balance control through performing head, trunk, and arm movements simultaneously with weight shifting.[7] Older people living in the community who participated in a Tai Chi group program report a reduced fear of falling compared to those who do not exercise, perhaps because the training leads to an increased self-awareness of balance.[7,168] However, Tai Chi training is unlikely to improve dynamic balance during functions such as gait and turning.[7,85] This may explain why there is conflicting evidence as to whether Tai Chi reduces falls or the risk of falls among people over the age of 50.[85,88] For this reason, Tai Chi should be considered as only one part of a comprehensive fall prevention program rather than being advocated as the sole exercise intervention.

Evidence-Based Balance Exercise Programs for Specific Musculoskeletal Conditions

Evidence is growing that specific balance exercise programs can effectively prevent and/or treat balance control deficits associated with lower extremity and trunk injuries and pathologies.

Ankle Sprains

Several systematic reviews have concluded that balance training programs can improve static and dynamic balance and reduce the risk of ankle sprains in individuals with a history of ankle sprains.[58,69,94,158] Successful programs utilized wobble or unstable balance platforms, single-leg stance progressions, and resisted kicks of the uninvolved leg against an elastic band or tubing.[38,52,93,99,126,155] Programs typically were conducted for at least three times per week throughout a competitive season for prevention or two to three times per week for approximately 6 to 8 weeks post injury.

FOCUS ON EVIDENCE

A balance program developed by McGuine and Keene[93] reduced the risk of ankle sprains by 38% in male (n=112) and female (n=261) high school soccer and basketball players. Participants performed the single-leg stance (Fig. 8.25), progressing from standing on the floor to standing on a wobble board with and without eyes open. They performed the balance activities 5 days a week for the first 5 weeks and then 3 days a week for the rest of the season. Each exercise was performed for a duration of 30 seconds per leg, and legs were alternated during a rest period of 30 seconds between repetitions.

FIGURE 8.25 Balance program for reducing the incidence of ankle sprains in athletes using a wobble board: **(A)** single-leg squat (knee bent 30° to 45°), **(B)** single-leg stance while rotating the board; and **(C)** single-leg stance while performing functional activities (i.e., catching a ball).

Anterior Cruciate Ligament Injuries

Proprioceptive and balance training programs either alone or in combination with neuromuscular training that includes lower extremity plyometrics, trunk stabilization, strengthening (refer to Chapter 16), and sport-specific functional training (refer to Chapters 21 and 23) have been shown to reduce risk factors and the incidence of first-time noncontact anterior cruciate ligament (ACL) injuries in athletes.[2,115,143] These proprioceptive and balance training programs frequently consisted of double and single leg balance exercises progressing from firm to unstable surfaces, such as ankle disks, tilt boards, or foam, with variations, such as squatting or catching a ball.[22, 40, 46, 95] Balance exercises usually were done 10 to 15 minutes daily during preseason training and 3 times a week during the season for prevention.

A balance training program developed by Fitzgerald and colleagues[41] that consisted of multidirectional perturbations manually applied by a therapist while a person stood with one or two legs on tilt or roller boards increased the likelihood by almost five times that a person with acute anterior cruciate ligament injury or ruptures of anterior ligament grafts would return to high-level physical activity compared to those that

received a standard program. Treatment in this study was done two to three sessions per week for a total of 10 sessions.

Low Back Pain

Research indicates that proprioceptive or balance training may improve postural control in individuals with low back pain.[20,39,92,149,150] Specific spinal stabilization exercises consisting of voluntary contractions of deep abdominal muscles reduced pain and disability[92] and produced immediate and long-term improvements in feedforward postural adjustments in people with chronic nonspecific low back pain (refer to Chapters 15 and 16).[149,150]

Cacciatore and associates[20] studied the effects of a 6-month, once a week course of 20 lessons in the Alexander Technique (AT), a technique that addresses anticipatory postural adjustments through conscious control of tonic muscular activity, on postural coordination and back pain in a 49-year-old woman with a 25-year history of left-sided, idiopathic low back pain. Before the AT lessons, the patient consistently had asymmetrical automatic postural responses to horizontal force platform movements and poor ability to balance on the left leg. Following the lessons, she had improved postural responses, better standing balance, and decreased low back pain.

Independent Learning Activities

Critical Thinking and Discussion

1. A person is experiencing falls when rising from a chair. Using biomechanical principles of balance, what adjustments can the person immediately make to increase his or her stability and prevent falls?
2. Differentiate and describe several balance movements that rely primarily on feedforward or open-loop motor control versus those that utilize closed-loop control.
3. Review the ankle, hip, and stepping strategies and discuss how the strategies are elicited and what key muscles are activated to control balance.
4. Think about the times you have fallen in the past. What activity were you doing at the time that you fell? What musculoskeletal, neurological, and/or contextual factors contributed to the fall occurrence? What were the consequences of the fall? What differences would you expect between your falls and those experienced by an elderly person?
5. Differentiate and discuss treatment activities that you would use to train static, dynamic, anticipatory, reactive, and sensory organization aspects of balance control. Provide examples of how you would progress each of the activities.
6. For an elderly person with a history of falls, what aspects of the home environment might need to be modified to maximize the individual's safety and independence?
7. The success of balance training programs depends on the compliance by the patient. What strategies would you use to increase the likelihood that a person would adhere to a home exercise program and ensure that his or her treatment outcomes are attained? Refer to Chapter 1 for discussion on teaching strategies for effective exercise.

Laboratory Practice

1. With a partner, mount a yardstick on the wall at the person's shoulder height. Measure the maximum amount of anterior and posterior sway by recording the maximum shoulder displacement during a 30-second period of quiet stance in each of the following conditions.
   - Standing on a firm surface with feet together, arms on hips, and eyes open.
   - Standing on a firm surface with feet together, arms on hips, and eyes closed
   - Standing on a soft foam surface with feet together, arms on hips, and eyes open
   - Standing on a soft foam surface with feet together, arms on hips, and eyes closed

   For each of the conditions, what sensory inputs are available to the person for maintaining balance? How does the amount of sway vary with each condition and why?

2. With a partner, observe body movement during the following activities.
   - Standing with feet shoulder width apart, perform self-initiated forward and backward body sways progressing from small to large amplitudes.
   - Standing with feet apart, have your partner place his or her hand on your sternum and nudge you backward gently and then again with a larger force.
   - Standing with the feet placed heel to toe, have your partner gently nudge you backward.
   - Put on ankle-foot orthoses or ski boots that restrict ankle movements and have your partner gently nudge you backward.

   Which movement strategy is elicited with each activity and why?

3. Practice performing treatment activities that you would use to train static, dynamic, anticipatory, reactive, and sensory organization aspects of balance control as described in Table 8.2. Progress each of the activities to maximally challenge your balance.

Case Studies

1. A 20-year-old male soccer player sustained a right mid-tibial fracture in a motor vehicle accident and was required to wear a long-leg rigid cast for 6 weeks. You are seeing the patient 1 week after cast removal for physical therapy. He would like to return to playing soccer but is currently unable to maintain balance on his right leg to kick a soccer ball.

What underlying impairments might be causing this individual's balance problems, and how would you design an exercise program that would allow him to reach his goals?

2. A 75-year-old woman fell in her bathtub and sustained a right pelvic fracture, requiring bed rest for 2 weeks. You are seeing the patient in her home following her hospital discharge. She has generalized weakness, deconditioning, is unsteady on her feet, and is fearful of falling. Currently, she is using a walker for ambulation. Prior to her fall, she was completely independent in all activities of daily living and enjoyed going on walks in her neighborhood in the evenings. Design a progressive balance program for this woman to restore her to her prior level of functioning.
3. A 70-year-old retiree has had bilateral knee replacement surgeries. He would like to resume his favorite hobby of boating but lacks confidence in his ability to balance under dynamic conditions. Design an exercise and balance training program that will help him return to his recreational pursuits. What suggestions do you have to increase his safety when boating? What if his hobby was golfing instead of boating? Compare and contrast the activities and exercises you would prescribe for these two different issues.
4. A 56-year-old obese woman with diabetes is being treated for low back pain. She reports unsteadiness when walking, particularly in darkened environments. She has difficulty maintaining her balance during Conditions 2, 3, 5, and 6 of the CTSIB test. What factors could be contributing to her unsteadiness? Design an exercise program that addresses her balance impairments.
5. An active, vibrant 70 year-old-female seeks your advice on how to best maintain her health and fitness. What are the major components of a comprehensive exercise program for her? Give examples of exercises she should include.

CHAPTER

9

Aquatic Exercise

ELAINE L. BUKOWSKI, PT, DPT, MS, (D)ABDA EMERITUS

Aquatic therapy, the use of water for rehabilitation purposes, traces its origin back several centuries. The use of water for restorative purposes has grown in popularity and has gained increased use in facilitating therapeutic exercise. The unique properties of the aquatic environment provide clinicians with treatment options that may otherwise be difficult or impossible to implement on land. Using buoyant devices and varied depths of immersion the practitioner has flexibility in positioning the patient (supine, seated, kneeling, prone, sidelying, or vertically) with any desired amount of weight bearing. Aquatic exercise has been successfully used for a wide variety of rehabilitation populations including pediatric,[6,27,37,54,75,79,85] orthopedic,[*] neurological,[41,57,63] and cardiopulmonary patients.[19,51,78]

[*]2,7,10,11,16,17,28,29,41,52,53,64,71,73,77,81

Background and Principles for Aquatic Exercise

Definition of Aquatic Exercise

Aquatic exercise refers to the use of water (in multidepth immersion pools or tanks) that facilitates the application of established therapeutic interventions, including stretching, strengthening, joint mobilization, balance and gait training, and endurance training.

Goals and Indications for Aquatic Exercise

The specific purpose of aquatic exercise is to facilitate functional recovery by providing an environment that augments a patient's and/or practitioner's ability to perform various therapeutic interventions. Aquatic exercise can be used to achieve the following specific goals:

- Facilitate range of motion (ROM) exercise[14,31,43,83]
- Initiate resistance training[14,20,40,43,62,68,82]
- Facilitate weight-bearing activities[2]
- Enhance delivery of manual techniques[3,72]
- Provide three-dimensional access to the patient[69,72]
- Facilitate cardiovascular exercise[13,59,60,74]
- Initiate functional activity replication[14,58,83]
- Minimize risk of injury or reinjury during rehabilitation[25,83]
- Enhance patient relaxation[31,48]

Although research studies support these goals for aquatic exercise, Hall and associates[41] cited the need for more research with robust designs that address temperature, depth of immersion, and care settings.

Precautions and Contraindications to Aquatic Exercise

Most patients easily tolerate aquatic exercise. However, the practitioner must consider several physiological and psychological aspects of immersion that affect selection of an aquatic environment.

Precautions

Fear of Water

Fear of water can limit the effectiveness of any immersed activity. Fearful patients often experience increased symptoms during and after immersion because of muscle guarding, stress response, and improper form with exercise. Often patients require an orientation period designed to provide instruction regarding the effects of immersion on balance, control of the immersed body, and proper use of flotation devices.[58]

Neurological Disorders

Ataxic patients may experience increased difficulty controlling purposeful movements. Patients with heat-intolerant multiple sclerosis may fatigue with immersion in temperatures greater than 33°C.[12,59,61] Patients with controlled epilepsy require close monitoring during immersed treatment and must be compliant with medication prior to treatment.[49,69]

Respiratory Disorders

Water immersion may adversely affect the breathing of the patient with a respiratory disorder. Lung expansion tends to be inhibited due to hydrostatic pressure against the chest wall. Additionally, increased circulation in the chest cavity may further inhibit lung expansion due to increased circulation to the center of the body. Maximal oxygen uptake is lower during most forms of water exercise than during land exercise.[69]

FOCUS ON EVIDENCE

Although the above precautions have been cited, Kurabayashi and associates[51] compared nose and mouth immersion to non-immersion. Participants spent 30 minutes/day for five days/week for two months in the pool with water temperature set at 38°C. There was a significant difference in the immersion group with increased %FVC ($p=0.058$), increased $FEV_{1.0\%}$ ($p=0.018$), increased peak flow ($p=0.039$), and increased P_{ao2} ($p=0.010$). Based on their findings, they recommended the use of subtotal immersion to improve respiratory function for individuals with chronic pulmonary emphysema. Pechter and colleagues[60] compared 30 minutes of water-based aerobics to land-base aerobics done twice weekly for 12 weeks. The water-based group demonstrated increases in peak VO_2, peak O_2 pulse, peak ventilation, and peak load, as well as decreases in serum creatinine, glomerular filtration rate, cystatin-c in serum, protein/creatinine ratio, systolic and diastolic blood pressure, total serum cholersterol, and serum triglycerides. They recommended the use of low-intensity aquatic exercise to improve cardiorespiratory and renal function in individuals with chronic renal failure.

Cardiac Dysfunction

Patients with angina, abnormal blood pressure, heart disease, or compromised pump mechanisms also require close monitoring.[19,78,80]

FOCUS ON EVIDENCE

Meyer and Leblanc[55] provided an algorithm for clinical decision-making when prescribing aquatic therapy for patients with left ventricular dysfunction and/or stable congestive heart failure. In their review of the literature, they suggested the following for rehabilitation and secondary prevention: 1) Temporary abnormal hemodynamic responses may be elicited by immersion to the neck. 2) Water therapy is absolutely contradindicated in patients with decompensated congestive heart failure. 3) Feeling good in water does not equate with left ventricular toleration of increased volume loading caused by immersion. 4) If patients with previous severe myocardial infarctions and/or congestive heart failure can sleep supine, they may be able to tolerate bathing in a half-sitting position provided immersion does not exceed the xiphoid process. 5) Patients with Q-wave myocardial infarctions older than

6 weeks may exercise in a pool for orthopedic reasons provided they do so in an upright position and immersion does not exceed the xiphoid process.

Small, Open Wounds and Lines

Small, open wounds and tracheotomies may be covered by waterproof dressings. Patients with intravenous lines, Hickman lines, and other open lines require proper clamping and fixation.[69] Precautions should also be exercised with patients having G-tubes and suprapubic appliances. Observation for adverse reactions to aquatic therapy is essential.[15]

Contraindications

Contraindications to aquatic therapy include any situation creating the potential for adverse effects to either the patient or the water environment.[8] Such factors include:

- Incipient cardiac failure and unstable angina.
- Respiratory dysfunction, vital capacity of less than 1 liter.
- Severe peripheral vascular disease.
- Danger of bleeding or hemorrhage.
- Severe kidney disease (patients are unable to adjust to fluid loss during immersion).
- Open wounds without occlusive dressings, colostomy, and skin infections, such as tinea pedis and ringworm.
- Uncontrolled bowel or bladder (bowel accidents require pool evacuation, chemical treatment, and possibly drainage).
- Menstruation without internal protection.
- Water and airborne infections or diseases (examples include influenza, gastrointestinal infections, typhoid, cholera, and poliomyelitis).
- Uncontrolled seizures during the last year (they create a safety issue for both clinician and patient if immediate removal from the pool is necessary).[15]

Properties of Water

The unique properties of water and immersion have profound physiological implications in the delivery of therapeutic exercise. To utilize aquatics efficiently, practitioners must have a basic understanding of the clinical significance of the static and dynamic properties of water as they affect human immersion and exercise.

Physical Properties of Water

The properties provided by buoyancy, hydrostatic pressure, viscosity, and surface tension have a direct effect on the body in the aquatic environment.[9,24,32,38,56]

Buoyancy (Fig. 9.1)

Definition. Buoyancy is the upward force that works opposite to gravity.

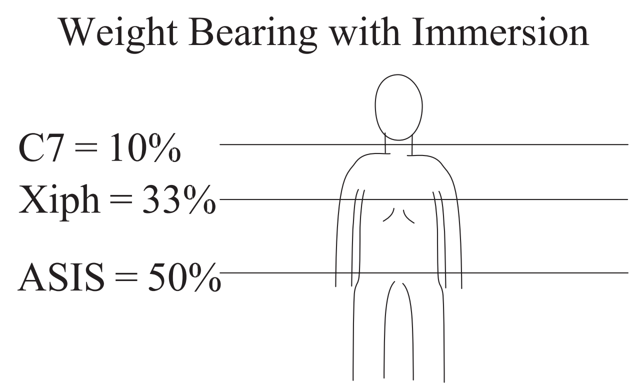

FIGURE 9.1 Percentage of weight bearing at various immersion depths.

Properties. Archimedes' principle states that an immersed body experiences upward thrust equal to the volume of liquid displaced.[32]

Clinical significance. The effects of buoyancy include the following.

- Buoyancy provides the patient with relative weightlessness and joint unloading by reducing the force of gravity on the body. In turn, this allows the patient to perform active motion with increased ease.
- Buoyancy provides resistance to movement when an extremity is moved against the force of buoyancy. This technique can be used to strengthen muscles.
- The amount of air in the lungs will affect buoyancy of the body. Buoyancy will be increased with fully inflated lungs and decreased with deflated lungs.
- Body composition will also affect buoyancy. Obese patients will have increased buoyancy due to fat tissue having a lower specific gravity. Patients with increased bone density will have less buoyancy than those with decreased bone density.
- Buoyancy allows the practitioner three-dimensional access to the patient.

CLINICAL TIP

Rotator cuff pathology. A patient recovering from rotator cuff repair can use the buoyancy force to increase range of motion in shoulder abduction and/or flexion while performing the motion in neck-deep water.[11] When performing shoulder extension from a 90° flexed position, the force of buoyancy becomes a resistance as the patient pulls the arm downward through the water.

Hydrostatic Pressure

Definition. Hydrostatic pressure is the pressure exerted by the water on immersed objects.

Properties. Pascal's law states that the pressure exerted by fluid on an immersed object is equal on all surfaces of the object. As the density of water and depth of immersion increase, so does hydrostatic pressure.

Clinical significance. The effects of hydrostatic pressure include the following.

- Increased pressure reduces or limits effusion, assists venous return, induces bradycardia, and centralizes peripheral blood flow.
- The proportionality of depth and pressure allows patients to perform exercise more easily when closer to the surface.

CLINICAL TIP

Regulation of performance. Barbosa and colleagues[4] compared the physiological adaptations of aquatic exercise with different levels of immersion to land exercise. Participants performed the same exercise on land, immersed to the hip, and immersed to the breast for 6 minutes. Physiological responses were higher when exercising immersed to the hip than when immersed to the breast and when exercising on land than immersed to either depth. The clinician should consider a progression from immersion to breast to immersion to hip to exercises on land to increase the physiological demands on the patient.

Viscosity

Definition. Viscosity is friction occurring between molecules of liquid resulting in resistance to flow.

Properties. Resistance from viscosity is proportional to the velocity of movement through liquid.

Clinical significance. Water's viscosity creates resistance with all active movements.

- Increasing the velocity of movement increases the resistance.
- Increasing the surface area moving through water increases resistance.

CLINICAL TIP

Lymphedema. Jamison[46,47] cited the effectiveness of hydrostatic pressure and viscosity for increasing lymph flow and reducing edema in patients with lymphedema. However, caution is needed as the dependent position of the extremity may cancel this effect. Recommended aquatic activities include Watsu® (a form of water Zen Shiatsu incorporating stretches that release blockages and produce relaxation), Jahara, Ai Chi (a form of water Tai Chi), water aerobics, Halliwick Method® (a technique that increases balance, strength, coordination, and flexibility), and aquatic proprioceptive neuromuscular facilitation (PNF). The reader is referred to the following list of references for further information on these interventions:

- Aquatic PNF: Jamison, L, and Ogden, D: *Aquatic Therapy Using PNF Patterns.* Tuscon, AZ: Therapy Skills Builders, 1994.

Surface Tension

Definition. The surface of a fluid acts as a membrane under tension. Surface tension is measured as force per unit length.

Properties. The attraction of surface molecules is parallel to the surface. The resistive force of surface tension changes proportionally to the size of the object moving through the fluid surface.

Clinical significance. The effect of surface tension includes the following.

- An extremity that moves through the surface performs more work than if kept under water.
- Using equipment at the surface of the water increases the resistance.

Hydromechanics

Definition. Hydromechanics comprise the physical properties and characteristics of fluid in motion.[38]

Components of flow motion. Three factors affect flow; they are laminar flow, turbulent flow, and drag.

- *Laminar flow.* Movement in which all molecules move parallel to each other, typically slow movement.
- *Turbulent flow.* Movement in which molecules do not move parallel to each other, typically faster movements.
- *Drag.* The cumulative effects of turbulence and fluid viscosity acting on an object in motion.

Clinical significance of drag. As the speed of movement through water increases, resistance to motion increases.[5,42]

- Moving water past the patient requires the patient to work harder to maintain his or her position in pool.
- Application of equipment (glove/paddle/boot) increases drag and resistance as the patient moves the extremity through water.[62]

CLINICAL TIP

Increasing resistance to motion. If the goal is to increase muscular force production during the early part of knee extension, the clinician should consider the use of a hydro-boot or similar device to increase the drag force on the leg/foot. Barbosa and associates[5] measured hydrodynamic drag in barefoot and hydro-boot conditions to determine the coefficients of drag on a human leg/foot model during simulated knee extension-flexion exercise. The influence of water resistance created higher drag force when using the hydro-boot during the early part of extension.

Thermodynamics

Water temperature has an effect on the body and, therefore, on performance in an aquatic environment.[42]

Specific Heat

Definition. Specific heat is the amount of heat (calories) required to raise the temperature of 1 gram of substance by 1°C.[38]

Properties. The rate of temperature change is dependent on the mass and the specific heat of the object.

Clinical significance. Water retains heat 1000 times more than air. Differences in temperature between an immersed object and water equilibrate with minimal change in the temperature of the water.

Temperature Transfer

- Water conducts temperature 25 times faster than air.
- Heat transfer increases with velocity. A patient moving through the water loses body temperature faster than an immersed patient at rest.

Center of Buoyancy (Fig. 9.2)

Center of buoyancy, rather than center of gravity, affects the body in an aquatic environment.[31,37,56]

Definition. The center of buoyancy is the reference point of an immersed object on which buoyant (vertical) forces of fluid predictably act.

Properties. Vertical forces that do not intersect the center of buoyancy create rotational motion.

Clinical significance. In the vertical position, the human center is located at the sternum.

- In the vertical position, posteriorly placed buoyancy devices cause the patient to lean forward; anterior buoyancy causes the patient to lean back.
- During unilateral manual resistance exercises, the patient revolves around the practitioner in a circular motion.

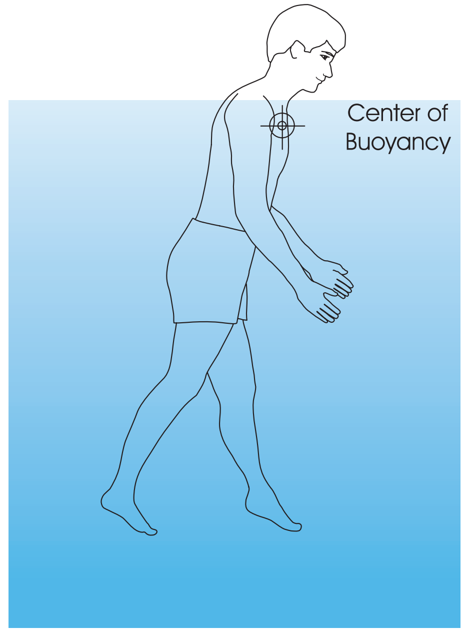

FIGURE 9.2 Center of buoyancy.

- A patient with a unilateral lower extremity amputation leans toward the residual limb side when in a vertical position.
- Patients bearing weight on the floor of the pool (i.e., sitting, kneeling, standing) experience aspects of both the center of buoyancy and center of gravity.

Aquatic Temperature and Therapeutic Exercise

A patient's impairments and the intervention goals determine the water temperature selection. In general, utilize cooler temperatures for higher-intensity exercise and utilize warmer temperatures for mobility and flexibility exercise and for muscle relaxation.[15,26,50,69] The ambient air temperature should be 3°C higher than the water temperature for patient comfort. Incorrect water or ambient air temperature selection may adversely affect a patient's ability to tolerate or maintain immersed exercise.

Temperature Regulation

- Temperature regulation during immersed exercise differs from that during land exercise because of alterations in temperature conduction and the body's ability to dissipate heat.[15,26,69] With immersion there is less skin exposed to air, resulting in less opportunity to dissipate heat through normal sweating mechanisms.
- Water conducts temperature 25 times faster than air[9]—more if the patient is moving through the water and molecules are forced past the patient.

- Patients perceive small changes in water temperature more profoundly than small changes in air temperature.
- Over time, water temperature may penetrate to deeper tissues. Internal temperature changes are known to be inversely proportional to subcutaneous fat thickness.[9]
- Patients are unable to maintain adequate core warmth during immersed exercise at temperatures less than 25˚C.[9,22]
- Conversely, exercise at temperatures greater than 37˚C may be harmful if prolonged or maintained at high intensities. Hot water immersion may increase the cardiovascular demands at rest and with exercise.[70]
- In waist-deep water exercise at 37˚C, the thermal stimulus to increase the heart rate overcomes the centralization of peripheral blood flow due to hydrostatic pressure.
- At temperatures greater than or equal to 37˚C, cardiac output increases significantly at rest alone.[15,18]

Mobility and Functional Control Exercise

- Aquatic exercises, including flexibility, strengthening, gait training, and relaxation, may be performed in temperatures between 26˚C and 35˚C.[9,15,69]
- Therapeutic exercise performed in warm water (33˚C) may be beneficial for patients with acute painful musculoskeletal injuries because of the effects of relaxation, elevated pain threshold, and decreased muscle spasm.[9,15,69]

Aerobic Conditioning

Cardiovascular training and aerobic exercise should be performed in water temperatures between 26˚C and 28˚C. This range maximizes exercise efficiency, increases stroke volume, and decreases heart rate.[18,69,76]

- Intense aerobic training performed above 80% of a patient's maximum heart rate should take place in temperatures between 22˚C and 26˚C to minimize the risk of heat illness.[18,69,76]

CLINICAL TIP

There are several considerations for immersion times and pool temperatures.[12,26,66,80]

Because of the increased demands placed on the patient's temperature regulating systems when exercising in a pool the following are recommended.

- Generally use a maximum immersion time of 20 minutes for patients with non-compromised cardiopulmonary systems. Begin with 10-minute sessions and increase the time as tolerated.
- Always monitor vital signs to ensure patient safety.
- Generally water temperatures between 36°C and 37°C are considered high and between 26°C and 35°C are considered low. In addition to the following guidelines, the patient's fatigue factor needs to be considered.
- Higher temperatures are recommended for patients with rheumatoid arthritis except in the acute stage.
- Lower temperatures are recommended for patients with spasticity or for those whose immersion time lasts 20 to 45 minutes.
- For general flexibility, strengthening, gait training and relaxation, the range may be between 26˚C and 35˚C.[9,15,69]
- Cardiovascular training and aerobic exercise should be performed in water temperatures between 26˚C and 28˚C.

Pools for Aquatic Exercise

Pools used for aquatic therapy vary in shape and size. The rooms in which pools are housed need to be adequately ventilated to avoid the accumulation of condensation on walls, windows, and floors. A dressing room should be provided for changing clothes and showering.

Traditional Therapeutic Pools (Fig. 9.3)

Traditional therapeutic pools measure at least 100 feet in length and 25 feet in width. Depth usually begins at 3 to 4 feet with a sloping bottom, progressing to 9 or 10 feet.

- This larger type pool may be used for groups of patients and the therapists conducting the session while in the pool.
- Entrance to larger therapeutic pools includes ramps, stairs, ladders, or mechanical overhead lifts.
- These pools have built-in chlorination and filtration systems.

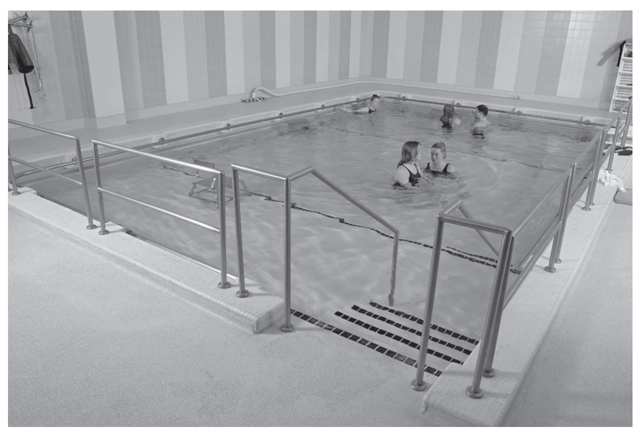

FIGURE 9.3 Traditional therapeutic pool. *(Courtesy of F.A. Davis Co., Philadelphia, PA.)*

Individual Patient Pools (Fig. 9.4)

Pools designed for individual patient use are usually smaller, self-contained units.

- These self-contained pools are entered via a door or one to two steps on the side of the unit.

FIGURE 9.4 Hydro Track©, self-contained underwater treadmill system. *(Courtesey of Ferno-Washington Inc., Wilmington, OH.)*

- The therapist provides instructions or cueing from outside the unit.
- In addition to built-in filtration systems, these units may include treadmills, adjustable currents, and varying water depths.

Special Equipment for Aquatic Exercise

A large variety of equipment exists for use with aquatic exercise. Aquatic equipment is used to provide buoyant support to the body or an extremity, challenge or assist balance, and generate resistance to movement. Resistive paddles, floats, paddle boards, and weighted stools and chairs are just a few of the many types of available equipment. By adding or removing equipment, the practitioner can progress exercise intensity. Type of equipment used is determined by the current functional level of the patient and the specific goals for the therapy session.

FIGURE 9.5 Cervical collar. *(Courtesy of Rothhammer International Inc., San Luis Obispo, CA.)*

Collars, Rings, Belts, and Vests

Equipment designed to assist with patient positioning by providing buoyancy assistance can be applied to the neck, extremities, or trunk. Inflatable cervical collars are used for the supine patient to support the neck and maintain the head out of the water (Fig. 9.5). Flotation rings come in various sizes and are used to support the extremities in any immersed position (Fig. 9.6). Often the rings are used at the wrists and ankles during manual techniques to assist with patient positioning and relaxation. Several types of belts exist that may be used to assist with buoyancy of an extremity or the entire body (Fig. 9.7). Belts and vests are used to position patients supine, prone, or vertically for shallow and deep water activities.

FIGURE 9.6 Flotation rings. *(Courtesy of Rothhammer International Inc., San Luis Obispo, CA.)*

FIGURE 9.7 Buoyancy belts. *(Courtesy of Rothhammer International Inc., San Luis Obispo, CA.)*

Swim Bars

Buoyant dumbbells (swim bars) are available in short and long lengths. They are useful for supporting the upper body or trunk in upright positions and the lower extremities in the supine or prone positions (Fig. 9.8). Patients can balance (seated or standing) on long swim bars in deep water to challenge balance, proprioception, and trunk strength.

Gloves, Hand Paddles, and Hydro-tone® Balls

Resistance to upper extremity movements is achieved by applying webbed gloves or progressively larger paddles to the hands (Fig. 9.9). These devices are not buoyant and, therefore, only resist motion in the direction of movement. Hydro-tone® bells are large, slotted plastic devices that increase drag during upper extremity motions. The bells generate substantially more resistance than gloves or hand paddles.

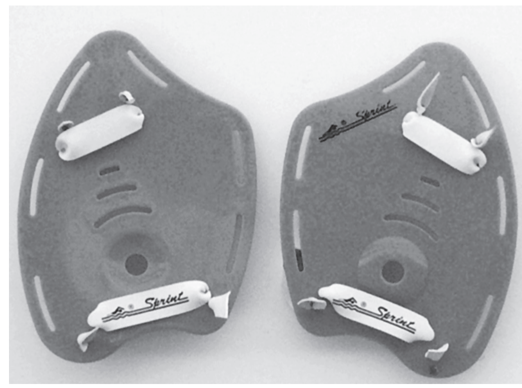

FIGURE 9.9 Hand paddles. *(Courtesy of Rothhammer International Inc., San Luis Obispo, CA.)*

Fins and Hydro-tone® Boots

The application of fins or boots to the feet during lower extremity motions generates resistance by increasing the surface area moving through the water. Fins are especially useful for challenging hip, knee, and ankle strength. Hydro-tone® boots are most effective during deep water walking and running (Fig. 9.10).

Kickboards

The shapes and styles of kickboards (Fig. 9.11) vary extensively among manufacturers. Nevertheless, kickboards remain a versatile and effective aquatic tool for augmenting any exercise program. Kickboards may be used to provide buoyancy

FIGURE 9.8 Swim bars. *(Courtesy of Rothhammer International Inc., San Luis Obispo, CA.)*

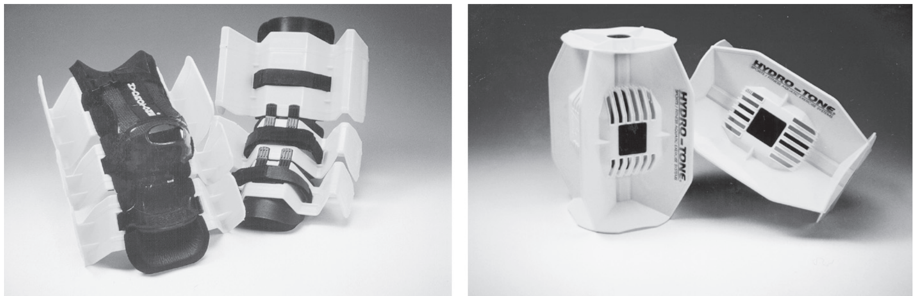

FIGURE 9.10 Hydro-tone® boots and bells. *(Courtesy of Rothhammer International Inc., San Luis Obispo, CA.)*

FIGURE 9.11 Kickboards. *(Courtesy of Rothhammer International Inc., San Luis Obispo, CA.)*

in the prone or supine positions, create resistance to walking patterns in shallow water when held vertically, or used to challenge seated, kneeling, or standing balance in the deep water.

Pool Care and Safety

Therapeutic pools require regular care and cleaning to avoid *Pseudomonas aeruginosa* (an infection causing folliculitis).[30,44,45] Frequent use increases the total organic carbon as well as ammonia and organic nitrogen found in the pool.

- Cleaning should occur at least twice weekly, and chlorine and pH level tests should be done twice daily.
- All walking surfaces near and around the pool should be slip-resistant and free of barriers. Water splashses should be dried immediately to prevent slips and falls.
- Safety rules and regulations are a must, as are emergency procedures, and should be posted and observed by all involved in therapeutic pool use.[84]
- Life preservers should be readily available and at least one staff member who is CPR certified should be present at all times.

CLINICAL TIP

Prior to the first therapeutic session, the treatment schedule, procedures to be used, and proper pool attire should be discussed with the patient. This is a good time to review their previous pool experiences and their expectations for the sessions, any bowel or bladder problems, use of any assistive or adaptive equipment, and medications.

Exercise Interventions Using an Aquatic Environment

Stretching Exercises

Patients may tolerate immersed stretching exercises better than land stretching because of the effects of relaxation, soft tissue warming, and ease of positioning.[14,17,31,43,83] However, buoyancy creates an inherently less stable environment than the land. Therefore, careful consideration is warranted when recommending aquatic stretching.

Manual Stretching Techniques

Manual stretching is typically performed with the patient supine in waist depth water with buoyancy devices at the neck, waist, and feet. Alternatively, the patient may be seated on steps. The buoyancy-supported supine position improves (versus land techniques) both access to the patient and control by the practitioner, as well as the position of the patient.

However, turbulence from wave activity can adversely affect both the patient's and the practitioner's ability to perform manual stretching. Difficulties may be experienced maintaining and perceiving the subtleties of end-range stretching and scapular stabilization in the supine buoyancy supported position. Anecdotal evidence indicates that careful

consideration of all factors is warranted prior to initiating manual stretching in an aquatic environment.[3,72]

The manual stretching techniques described in this section are considered passive techniques but may be adapted to utilize muscle inhibition techniques. The principles of stretching are the same as those discussed in Chapter 4.

The following terms are used to describe the stretching techniques.

- *Practitioner position.* Describes the orientation of the practitioner to the patient.
- *Patient position.* Includes buoyancy-assisted (BA) seated or upright positioning and buoyancy-supported (BS) supine positioning.
- *Hand placement.* The fixed hand, which stabilizes the patient, is typically the same (ipsilateral) hand as the patient's affected extremity, and it is positioned proximally on the affected extremity. The movement hand, which guides the patient's extremity through the desired motion and applies the stretch force, is typically the opposite (contralateral) hand as the patient's affected extremity and is positioned distally.
- *Direction of movement.* Describes the motion of the movement hand.

Spine Stretching Techniques

Cervical Spine: Flexion

Practitioner Position

Stand at the patient's head facing caudalward.

Patient Position

BS supine without cervical collar.

Hand Placement

Cup the patient's head with your hands, the forearms supinated and thumbs placed laterally. Alternatively, place your hands in a pronated position with the thumbs at the occiput. This results in a more neutral wrist position at end-range stretch.

Direction of Movement

As you flex the cervical spine, the patient has a tendency to drift away from you if care is not taken to perform the motion slowly.

Cervical Spine: Lateral Flexion (Fig. 9.12)

Practitioner Position

Stand at the side facing the patient.

Patient Position

BS supine without a cervical collar.

Hand Placement

Reach the fixed hand dorsally under the patient and grasp the contralateral arm; support the head with the movement hand.

Direction of Movement

Move the patient into lateral flexion and apply stretch force at desired intensity. This position prevents patient drift as the fixed hand stabilizes the patient against the practitioner.

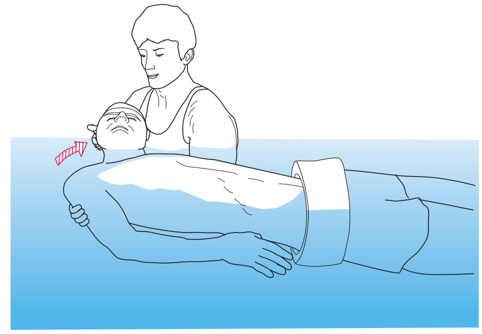

FIGURE 9.12 Hand placement and stabilization for stretching to increase cervical lateral flexion.

Thoracic and Lumbar Spine: Lateral Flexion/Side Bending (Fig. 9.13)

Practitioner Position

Stand on the side opposite that to be stretched, facing cephalad with ipsilateral hips in contact (e.g., if stretching the left side of the trunk, the therapist's right hip is against patient's right hip).

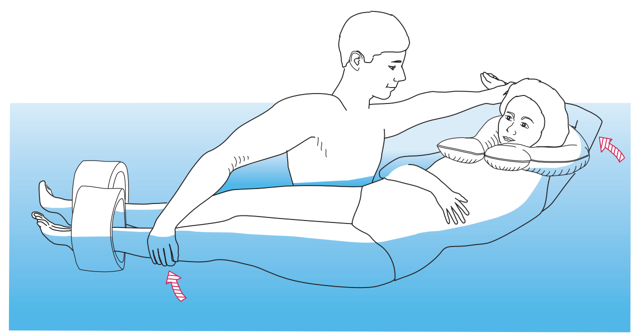

FIGURE 9.13 Hand placement and stabilization for stretching to increase lateral trunk flexion.

Patient Position

BS supine, if tolerated. The patient's stretch side arm is abducted to end-range to facilitate stretch.

Hand Placement

Grasp the patient's abducted arm with the fixed hand; alternately, grasp at the deltoid if patient's arm is not abducted. The movement hand is at the lateral aspect of the lower extremity of the side to be stretched (more distal placement improves leverage with stretch).

Direction of Movement

With the patient stabilized by your hip, pull the patient into lateral flexion. This technique allows variability in positioning and hand placement to isolate distinct segments of the spine.

Shoulder Stretching Techniques

Shoulder Flexion (Fig. 9.14)

Practitioner Position

Stand on the side to be stretched facing cephalad.

Patient Position

BS supine with the affected shoulder positioned in slight abduction.

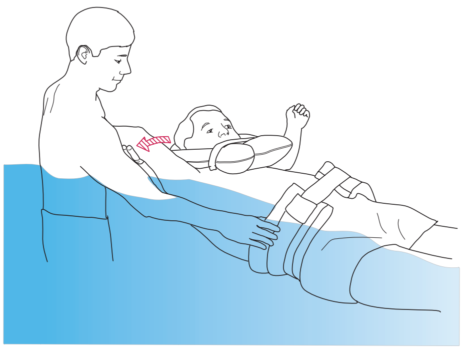

FIGURE 9.14 Hand placement and stabilization for stretching to increase shoulder flexion.

Hand Placement

Grasp the buoyancy belt with the fixed hand; the movement hand is at the elbow of the affected extremity.

Direction of Movement

After positioning the arm in the desired degree of abduction, direct the arm into flexion and apply the stretch force with the movement hand.

Shoulder Abduction

Practitioner Position

Stand on the affected side facing cephalad with your hip in contact with the patient's hip.

Patient Position

BS supine.

Hand Placement

Stabilize the scapula with the fixed hand; the movement hand grasps medially on the affected elbow joint.

Direction of Movement

Guide the arm into abduction and apply the stretch force. The hip contact provides additional stabilization as the stretch force is applied.

Shoulder External Rotation

Practitioner Position

Stand lateral to the affected extremity facing cephalad.

Patient Position

BS supine; position arm in desired degree of abduction with elbow flexed to 90°.

Hand Placement

Grasp the medial side of the patient's elbow with the palmar aspect of the fixed hand while fingers hold laterally; grasp the midforearm with the movement hand.

Direction of Movement

Movement hand guides forearm dorsally to externally rotate the shoulder and apply stretch force.

Shoulder Internal Rotation

Practitioner Position

Stand lateral to the patient's affected extremity facing caudalward.

Patient Position

BS supine; position arm in desired degree of abduction with elbow flexed to 90°.

Hand Placement

Stabilize the scapula with the dorsal aspect of the fixed hand entering from the axilla; the movement hand is at the distal forearm.

Direction of Movement

Direct the forearm palmarward and apply the stretch force. Use care to observe the glenohumeral joint to avoid a forward thrust and substitution.

Hip Stretching Techniques

Hip Extension

Practitioner Position

Kneel on one knee at the patient's affected side.

Patient Position

BS supine with the hip extended and the knee slightly flexed.

Hand Placement

Stabilize the patient's affected extremity by hooking the top of the foot with your ipsilateral thigh. Grasp the buoyancy belt with the movement hand and guide the motion with the fixed hand on the knee.

Direction of Movement

Direct the patient caudally with the movement hand. To increase the stretch on the rectus femoris, lower the patient's knee in the water. Motion is performed slowly to limit spinal and pelvic substitution.

Hip External Rotation

Practitioner Position

Face the lateral aspect of the patient's thigh with your ipsilateral arm under the patient's flexed knee.

Patient Position

BS supine; hip flexed 70° and knee flexed 90°.

Hand Placement

Grasp the buoyancy belt with the contralateral (fixed) hand while the ipsilateral (movement) hand grasps the thigh.

Direction of Movement
Externally rotate hip with the movement hand as the patient's body lags through water to create stretch force.

Hip Internal Rotation

Practitioner Position
Face the lateral aspect of the involved thigh with the ipsilateral arm under the flexed knee.

Patient Position
BS supine, hip flexed 70° and knee flexed 90°.

Hand Placement
Stabilize the buoyancy belt with the contralateral (fixed) hand while grasping the thigh with the ipsilateral (movement) hand.

Direction of Movement
Internally rotate the hip as the patient's body lags through water to create the stretch force.

Knee Stretching Techniques

Knee Extension with Patient on Steps

Practitioner Position
Half-kneel lateral to the affected knee with the ankle of the affected extremity resting on your thigh.

Patient Position
Semi-reclined on pool steps.

Hand Placement
Place one hand just proximal and one just distal to the knee joint.

Direction of Movement
Extend the patient's knee.

Knee Flexion with Patient on Steps

Practitioner Position
Half-kneel lateral to the affected knee.

Patient Position
Semi-reclined on pool steps.

Hand Placement
Grasp the distal tibia with the ipsilateral hand; the contralateral hand stabilizes the lateral aspect of affected knee.

Direction of Movement
The stretch force into flexion.

Knee Flexion with Patient Supine (Fig. 9.15)

Practitioner Position
Half-kneel lateral to the affected knee with the dorsal aspect of the patient's foot hooked under the ipsilateral thigh.

Patient Position
BS supine, affected knee flexed.

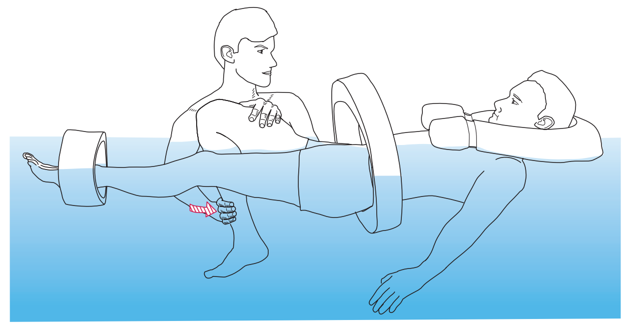

FIGURE 9.15 Hand placement and stabilization for stretching to increase knee flexion.

Hand Placement
Place the ipsilateral (fixed) hand on distal tibia and the contralateral (movement) hand on buoyancy belt to pull the body over the fixed foot.

Direction of Movement
Pull the patient's body over the fixed foot, creating the stretch to increase knee flexion. Lower the patient's knee into the water to extend the hip and increase the stretch on the rectus femoris. Perform the motion slowly to limit spinal and pelvic substitution.

Hamstrings Stretch

Practitioner Position
Face the patient and rest the patient's affected extremity on your ipsilateral shoulder.

Patient Position
BS supine, knee extended.

Hand Placement
Place both hands at distal thigh.

Direction of Movement
Start in the squatting position and gradually stand to flex the hip and apply the stretch force. Maintain knee extension by pulling the patient closer and increasing the stretch.

Self-Stretching with Aquatic Equipment

Often the intervention plan is to instruct the patient to perform independent stretching.[26,39,64,67] Self-stretching can be performed in either waist-deep or deep water. The patient frequently utilizes the edge of the pool for stabilization in both waist-depth and deep water.

Applying buoyancy devices may assist with stretching and increase the intensity of the aquatic stretch.[76,83] However, buoyancy devices are not required to achieve buoyancy-assisted stretching—that is, as buoyancy acts on any submersed extremity, correct patient positioning adequately produces a gentle stretch. The following guidelines describe the use of equipment for mechanical stretching; the descriptions apply

similarly for use without buoyancy equipment. Providing verbal cueing and visual demonstration for patient positioning and form aids in achieving the desired stretching effects.

Positioning for self-stretching of every body part is not described in this section. Typically, positioning for immersed self-stretches reflects traditional land positioning.

The following terms are used to describe the self-stretching techniques.

- *Patient position.* Includes buoyancy-assisted (seated/upright), buoyancy-supported (supine), or vertical.
- *Buoyancy-assisted.* Using the natural buoyancy of water to "float" the extremity toward the surface.
- *Equipment-assisted.* Includes use of buoyancy devices attached or held distally on an extremity.

The following are some examples of self-stretching.

Shoulder Flexion and Abduction

Patient Position

Upright, neck level immersion.

Equipment

Small or large buoyant dumbbell or wrist strap.

Direction of Movement

Grasping the buoyant device with the affected extremity allows the extremity to float to the surface as the buoyancy device provides a gentle stretch.

Hip Flexion (Fig. 9.16)

Patient Position

Upright, immersed to waist, or seated at edge of pool/on steps with hips immersed.

Equipment

Small buoyant dumbbell or ankle strap. For hip flexion with knee flexion, place strap/dumbbell proximal to the knee. For hip flexion with knee extension (to stretch the hamstrings), place strap/dumbbell at the ankle.

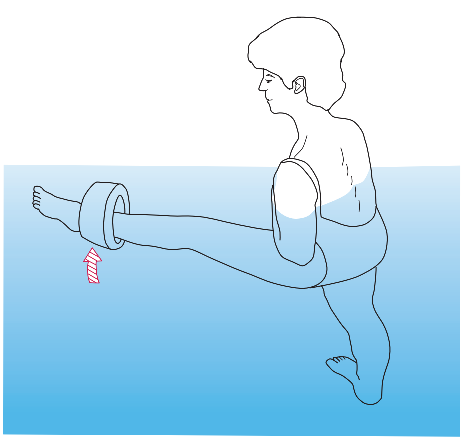

FIGURE 9.16 Self-stretching technique to increase hip flexion (stretch the hamstrings) using aquatic equipment.

Direction of Movement

Allow buoyancy device to float hip into flexion, applying stretch to hip extensors or hamstrings.

Knee Extension

Patient Position

Seated on steps/edge of pool with knee in a position of comfort.

Equipment

Small dumbbell or ankle strap.

Direction of Movement

Allow buoyancy device to extend knee toward the surface applying stretch to increase knee extension.

Knee Flexion

Patient Position

Stand immersed to waist with hip and knee in neutral position; increasing the amount of hip extension increases the stretch on the two joint knee extensors.

Equipment

Small dumbbell or ankle strap.

Direction of Movement

Allow buoyancy device to flex the knee toward the surface, applying stretch to knee extensors.

Strengthening Exercises

By reducing joint compression, providing three-dimensional resistance, and dampening perceived pain, immersed strengthening exercises may be safely initiated earlier in the rehabilitation program than traditional land strengthening exercises.[83] Both manual and mechanical immersed strengthening exercises typically are done in waist-depth water. However, some mechanical strengthening exercises may also be performed in deep water. Frequently, immersion alters the mechanics of active motion. For example, the vertical forces of buoyancy support the immersed upper extremity and alter the muscular demands on the shoulder girdle.[76] Furthermore, studies have demonstrated that lower extremity demand is inversely related to the level of immersion during closed-chain strengthening.[4,5,36]

Manual Resistance Exercises

Application of aquatic manual resistance exercises for the extremities typically occurs in a concentric, closed-chain fashion.[3,72] Manual aquatic resistance exercises are designed to fixate the distal segment of the extremity as the patient contracts the designated muscle group(s). The practitioner's hands provide primary fixation and guidance during contraction. As the patient contracts his or her muscles, the body moves over or away from the fixed distal segment (generally over the fixed

segment for the lower extremity and away from the fixed segment for the upper extremity). The patient's movement through the viscous water generates resistance, and the patient's body produces the drag forces. Verbal cueing by the practitioner is essential to direct the patient when to contract and when to relax, thereby synchronizing practitioner and patient.

Stabilization of the distal extremity segment is essential for maintaining proper form and isolating desired muscles. However, appropriate stabilization is not possible in the buoyancy-supported supine position for eccentric exercises or rhythmic stabilization of the extremities. The patient's body will have a tendency to tip and rotate in the water. In addition, the practitioner will have difficulty generating adequate resistance force, and the patient's body will move easily across the surface of the water with minimal drag producing inadequate counterforce to the practitioner's resistance. When supine, some motions, including horizontal shoulder adduction and abduction, should be avoided because of the difficulty the patient may have isolating proper muscle groups. Nevertheless, for many motions, the aquatic environment allows closed-chain resistive training through virtually limitless planes of motion.

The following terms refer to manual resistance exercise in water.

- *Practitioner position.* Describes the orientation of the practitioner to the patient.
- *Patient position.* Buoyancy-supported in the supine position.
- *Hand placement.* The guide hand is generally the ipsilateral hand as the patient's affected extremity and typically is positioned more proximally. It directs the patient's body as muscles contract to move the body through the water. The resistance hand is generally the contralateral hand and typically is placed at the distal end of the contracting segment. More distal placement increases overall resistance.
- *Direction of movement.* Describes the motion of the patient.

Upper Extremity Manual Resistance Techniques

Shoulder Flexion/Extension (Fig. 9.17 A & B)

Practitioner Position

Face caudal, lateral to the patient's affected shoulder.

Patient Position

BS supine; affected extremity flexed to 30°.

Hand Placement

Place the palmar aspect of the guide hand at the patient's acromioclavicular joint. The resistance hand grasps the distal forearm. An alternative placement for the resistance hand may be the distal humerus; this placement alters muscle recruitment.

Direction of Movement

Active shoulder flexion against the resistance hand causes the body to move away from the practitioner. Active shoulder extension from a flexed position causes the body to glide toward the practitioner.

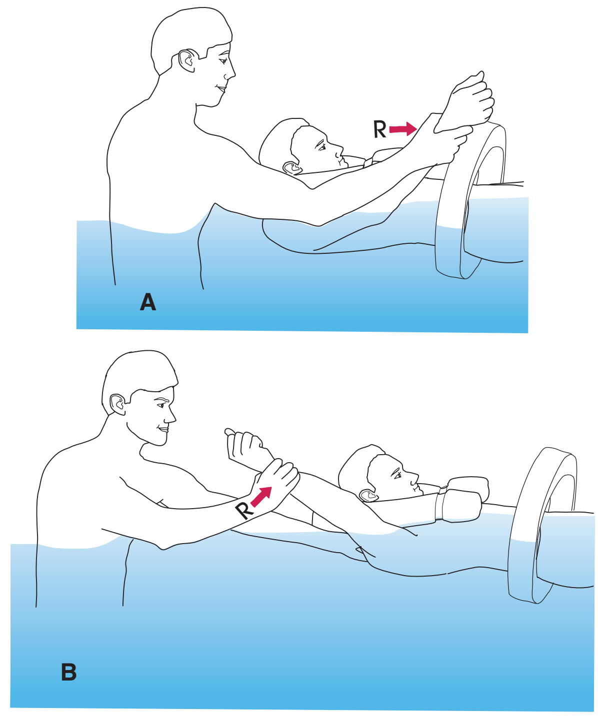

FIGURE 9.17 Manual resistance exercise for strengthening shoulder flexion. **(A)** start position and **(B)** end position.

NOTE: The patient must be able to actively flex through 120° for proper resistance to be provided.

Shoulder Abduction

Practitioner Position

Face medially, lateral to the patient's affected extremity.

Patient Position

BS supine; affected extremity in neutral.

Hand Placement

Place the palmar aspect of guide hand at the proximal humerus as the thumb wraps anteriorly and the fingers wrap posteriorly. Place the resistance hand at the lateral aspect of distal humerus.

Direction of Movement

The practitioner determines the amount of external rotation and elbow flexion. Active abduction against the resistance hand causes the body to glide away from the affected extremity and the practitioner.

Shoulder Internal/External Rotation (Fig. 9.18 A & B)

Practitioner Position

Face medially on the lateral side of the patient's affected extremity.

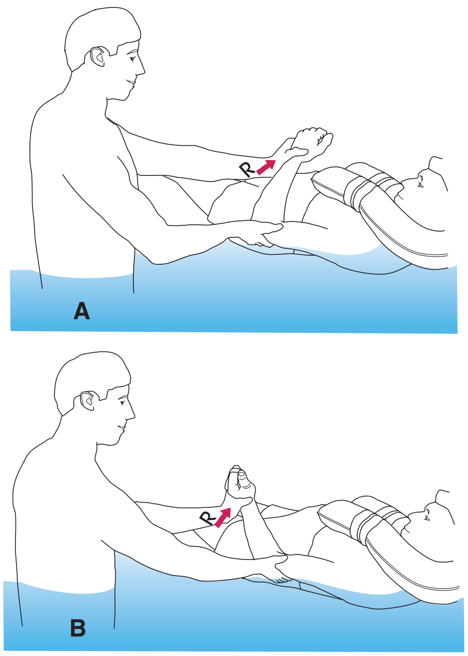

FIGURE 9.18 Manual resistance exercise for strengthening shoulder external rotation. **(A)** start position and **(B)** end position.

Patient Position

BS supine; affected extremity's elbow flexed to 90° with the shoulder in the desired amount of abduction and initial rotation.

Hand Placement

Place the palmar aspect of the guide hand at the lateral aspect of the elbow. The resistance hand grasps the palmar aspect of the distal forearm. An alternative method requires the practitioner to "switch" hands. The practitioner's ipsilateral hand becomes the guide hand and grasps the buoyancy belt laterally. The practitioner's contralateral hand becomes the resistance hand. This approach allows improved stabilization; however, the practitioner loses contact with the patient's elbow and must cue the patient to maintain the desired degree of shoulder abduction during the exercise.

Direction of Movement

Active internal rotation by the patient against the resistance hand causes the body to glide toward the affected extremity; active external rotation causes the body to glide away from the affected extremity.

Unilateral Diagonal Pattern: D_1Flexion/ Extension of the Upper Extremity

Practitioner Position

Stand lateral to the patient's unaffected extremity and face medially and caudally.

Patient Position

BS supine; affected extremity internally rotated and pronated with slight forward flexion.

Hand Placement

Secure the medial and lateral epicondyles of the distal humerus with the guide hand. Place the resistance hand on the dorsal surface of the distal forearm.

Direction of Movement

Prior to contraction, cue the patient to execute the specific joint motions expected in the diagonal patterns. Active contraction through the D_1flexion pattern causes the body to glide away from the practitioner. At the end position of D_1, secure the medial and lateral epicondyles of the distal humerus with the guide hand. The resistance hand will be on the palmar aspect of the distal forearm. From the flexed position, the practitioner cues the patient to contract through the D_1extension pattern.

Unilateral Diagonal Pattern: D_2Flexion/ Extension of the Upper Extremity (Fig. 9.19 A & B)

Practitioner Position

Stand lateral to the patient's affected shoulder; face medially and caudally.

Patient Position

BS supine; affected extremity adducted and internally rotated.

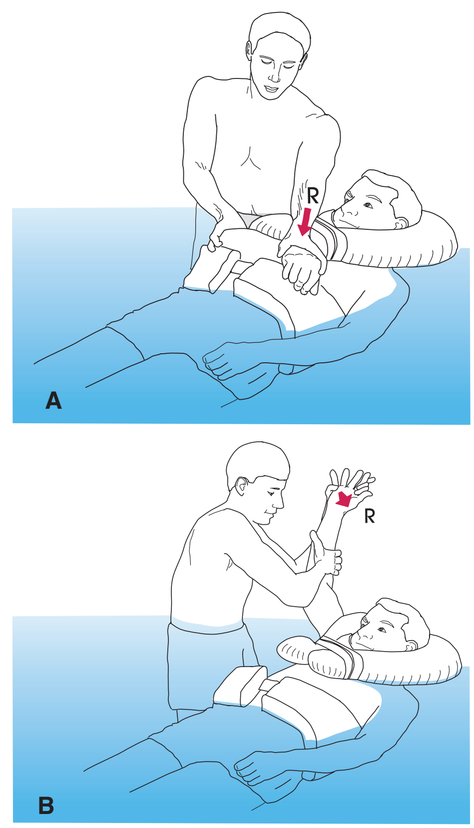

FIGURE 9.19 Manual resistance exercise for upper extremity unilateral diagonal D_2flexion pattern. **(A)** start position and **(B)** end position.

Hand Placement

Secure the medial and lateral epicondyles of the distal humerus with the guide hand. Wrap the palmar aspect of the resistance hand on the dorsal wrist medial to the palmar surface.

Direction of Movement

Active movement through the D_2flexion pattern causes the body to glide away from the practitioner. From the fully flexed position, cue the patient to then move into the D_2extension pattern. This causes the body to glide toward the practitioner.

Bilateral Diagonal Pattern: D_2Flexion/ Extension of the Upper Extremities (Fig. 9.20 A & B)

Practitioner Position

Stand cephalad to patient, facing caudally.

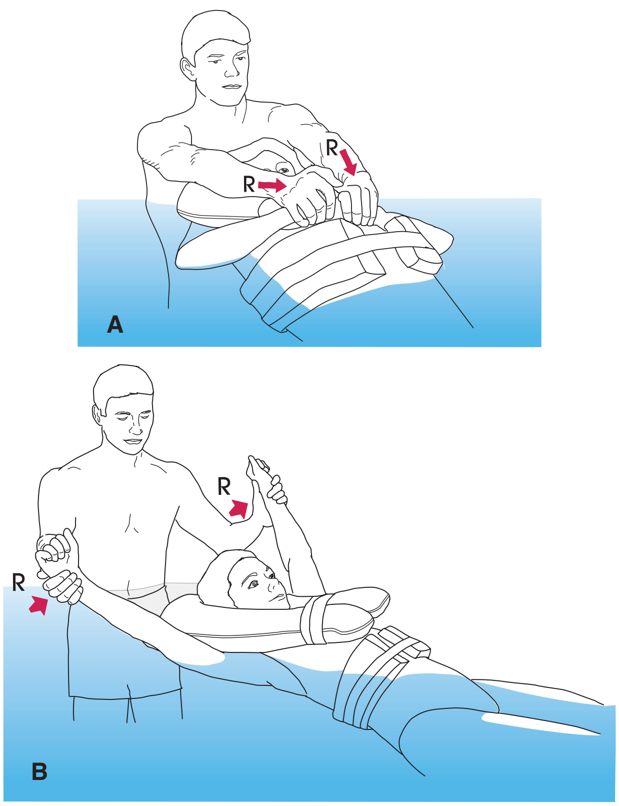

FIGURE 9.20 Manual resistance exercise for upper extremity bilateral diagonal D_2 pattern. (A) start position and (B) end position.

Patient Position

BS supine; upper extremities adducted and internally rotated.

Hand Placement

Use both hands to provide resistance. Grasp the dorsal aspect of each of the patient's wrists, wrapping medially to the palmar surface.

Direction of Motion

Active contraction through the D_2flexion pattern causes the body to glide away from the practitioner. From the fully flexed position, cue the patient to contract through D_2extension, causing the patient to move toward the practitioner.

Lower Extremity Manual Resistance Techniques

Hip Adduction

Practitioner Position

Stand lateral to the patient's affected extremity and face medially.

Patient Position

BS supine; hip abducted.

Hand Placement

Place the guide hand on the buoyancy belt and the resistance hand on the patient's medial thigh.

Direction of Movement

Active contraction of the hip adductors causes the affected leg to adduct as the contralateral leg and body glides toward the affected leg and the practitioner.

Hip Abduction (Fig. 9.21)

Practitioner Position

Stand lateral to patient's affected extremity, facing medially.

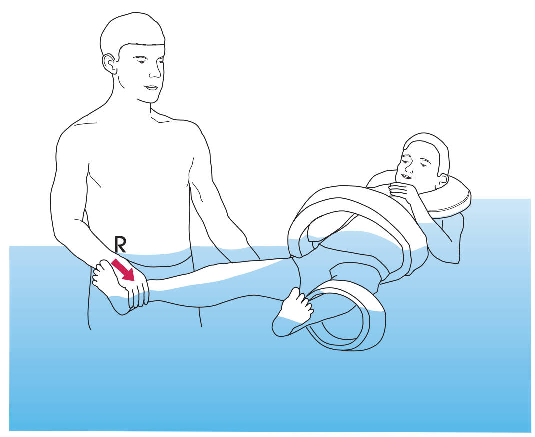

FIGURE 9.21 Manual resistance exercise for strengthening hip abduction with resistance applied to lateral aspect of the leg.

Patient Position

BS supine; hip adducted.

Hand Placement

Place the guide hand on the buoyancy belt or lateral thigh and the thumb and base of the resistance hand on the patient's lateral leg.

Direction of Movement

Active contraction of the hip abductors causes the affected leg to abduct as the contralateral leg and body glide away from the affected leg and the practitioner.

Hip Flexion with Knee Flexion (Fig. 9.22)

Practitioner Position

Stand at the side of the patient's affected extremity, facing cephalad.

Patient Position

BS supine.

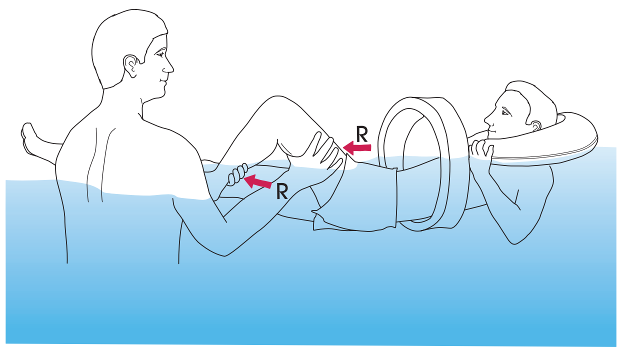

FIGURE 9.22 Manual resistance exercise for strengthening hip and knee flexion.

Hand Placement

Place the guide hand on the buoyancy belt or lateral hip. The resistance hand grasps proximal to the distal tibiofibular joint.

Direction of Movement

Active contraction of the hip and knee flexors causes the patient's body to glide toward the practitioner and fixed distal extremity.

Hip Internal/External Rotation

Practitioner Position

Stand lateral to the patient's affected extremity, facing medially.

Patient Position

BS supine; hip in neutral at 0° extension with knee flexed to 90°.

Hand Placement

Contact the distal thigh medially with the guide hand for resisted internal rotation and laterally for resisted external rotation. Place the resistance hand at the distal leg.

Direction of Movement

Active contraction of hip rotators (alternating between internal and external rotation) causes the patient's body to glide away from the distal fixed segment.

PRECAUTION: Avoid this exercise for patients with possible medial or lateral knee joint instability.

Knee Extension

Practitioner Position

Stand at the patient's feet, facing cephalad.

Patient Position

BS supine.

Hand Placement

Place the guide hand at the patient's lateral thigh and the resistance hand on the dorsal aspect of the distal tibiofibular joint.

Direction of Movement

Active contraction of the quadriceps against the practitioner's resistance hand directs the body away from the practitioner as the knee extends.

Ankle Motions

Practitioner Position

Stand lateral to the affected leg, facing caudally.

Patient Position

BS supine.

Hand Placement

The hand placement creates a short lever arm at the patient's ankle. As the patient moves through the resisted ankle motions, the patient's entire body moves through the water, producing a significant amount of drag and demand on the ankle complex.

PRECAUTION: For patients with ligamentous laxity and unstable ankles or compromised ankle musculature, the practitioner should cue the patient to avoid maximum effort during contraction to avoid potential injury.

Ankle Dorsiflexion and Plantarflexion

Hand Placement

Place the guide hand on the lateral aspect of the leg and the resistance hand over the dorsal aspect of the foot to resist dorsiflexion and on the plantar aspect to resist plantarflexion.

Direction of Movement

The body moves toward the practitioner during dorsiflexion and away from the practitioner during plantarflexion.

Ankle Inversion and Eversion

Hand Placement

Place the guide hand on the lateral aspect of the lower leg during inversion and on the medial aspect of tibia during eversion. To resist inversion, grasp the dorsal medial aspect of the foot and to resist eversion grasp the lateral foot.

Direction of Movement

During inversion, the body glides toward the practitioner, and during eversion, the body glide aways from the practitioner.

Dynamic Trunk Stabilization

By applying concepts utilized for spinal stabilization exercises on land (see Chapters 15 and 16), the practitioner can challenge the dynamic control and strength of the trunk muscles in the

aquatic environment. The BS supine position creates a unique perceptual environment for the patient.

Dynamic Trunk Stabilization: Frontal Plane (Fig. 9.23)

Practitioner Position

Hold the patient at the shoulders or feet.

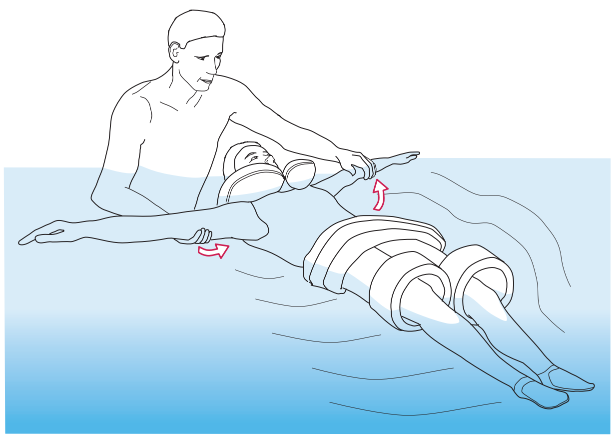

FIGURE 9.23 Isometric trunk stabilization exercise using side-to-side motions of the trunk.

Patient Position

Typically, the patient is placed in a supine position with buoyancy devices at the neck, waist, and legs.

Execution

Have the patient identify his or her neutral spine position, perform a "drawing-in maneuver" (see Chapter 16), and maintain the spinal position (isometric abdominal contraction). Move the patient from side to side through the water; monitor and cue the patient to avoid lateral trunk flexion, an indication that the patient is no longer stabilizing the spine.

Intensity

Moving the patient through the water faster increases drag and exercise intensity. Holding the patient more distally increases exercise intensity.

Dynamic Trunk Stabilization: Multidirectional

Practitioner Position

Stand at the shoulders or feet of the patient and grasp the patient's extremity to provide fixation as the patient contracts.

Patient Position

Typically, the patient is placed in a supine position with buoyancy devices at the neck, waist, and legs.

Execution

Instruct the patient to assume a neutral spine, perform the drawing-in maneuver, and "hold" the spine stable. Instruct the patient to perform either unilateral or bilateral resisted extremity patterns while maintaining a neutral spine and abdominal control. Monitor and cue the patient to avoid motion at the trunk, an indication that the patient is no longer stabilizing with the deep abdominal and global muscles. Upper extremity motions include shoulder flexion, abduction, and diagonal patterns. Lower extremity motions include hip and knee flexion and hip abduction and adduction.

Intensity

Unilateral patterns are more demanding than bilateral patterns. Increasing speed or duration increases exercise intensity.

Independent Strengthening Exercises

Often patients perform immersed strengthening exercises independently. Because the resistance created during movement through water is speed-dependent, patients are able to control the amount of work performed and the demands imposed on contractile elements.[35,42,69] Typically, positioning and performance of equipment-assisted strengthening activities in water reflect that of traditional land exercise. However, the aquatic environment allows patients to assume many positions (supine, prone, side-lying, seated, vertical). Attention to specific patient positioning allows the practitioner to utilize the buoyant properties of water and/or the buoyant and resistive properties of equipment that can either assist or resist patient movement.[11,26,50,62] Before initiating immersed strengthening activities, patients should be oriented to the effects of speed and surface area on resistance. Specific exercises for mechanical strengthening of every body part are not described. Only selected exercises are discussed and illustrated to reinforce major concepts and principles of application.

The following terms are used for equipment-assisted exercise.

- Buoyancy-assisted (BA): Vertical movement directed parallel to vertical forces of buoyancy that assist motion (patient may use buoyant equipment to assist with motion).
- Buoyancy-supported (BS): Horizontal movement with vertical forces of buoyancy eliminating or minimizing the need to support an extremity against gravity (patient may use buoyant equipment to assist with motion).
- Buoyancy-resisted (BR): Movement directed against or perpendicular to vertical forces of buoyancy, creating drag (performed without equipment).
- Buoyancy-superresisted (BSR): Use of equipment generates resistance by increasing the total surface area moving through water by creating greater drag. Increasing the speed of motion through water generates further drag.

Extremity Strengthening Exercises (Fig. 9.24 A, B, C, D, and E)

The most common aquatic upper and lower extremity strengthening exercises are outlined in Table 9.1.[26,50] Typically, patients are positioned standing immersed to shoulder level for upper extremity strengthening and to mid-trunk level for

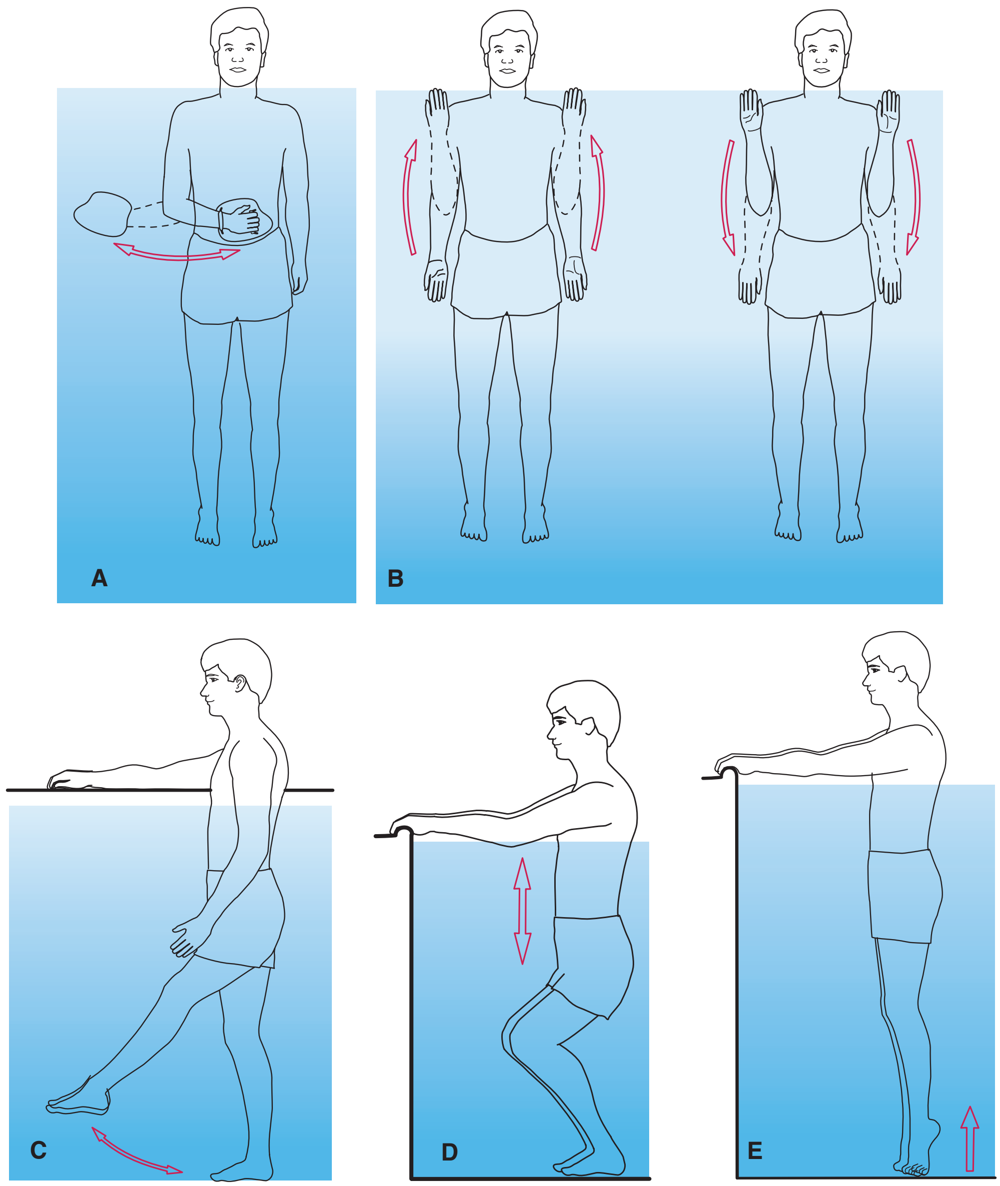

FIGURE 9.24 Mechanical resistance for strengthening **(A)** shoulder internal and external rotation, **(B)** elbow flexion and extension, **(C)** hip flexion and extension, **(D)** functional squatting, and **(E)** ankle plantarflexion.

lower extremity strengthening. However, many exercises may be performed with the patient positioned vertically in deep water. The prone or supine position is useful when practitioners wish to progress patients or when patients require position-specific or sports-specific strengthening. Some exercises, most notably bilateral lower extremity diagonals, require the patient to be positioned supine, prone, or vertical in deep water.

Lumbar Spine Strengthening

Spinal stabilization may be performed in shallow, mid-depth, or deep water levels. Typically, patients are instructed to maintain a neutral spine with the drawing-in maneuver (see Chapter 16) while performing functional activities or moving the extremities. The patient's ability to stabilize the spine can be challenged by increasing the duration of the activity, the speed or surface area moving through water, and by the addition of buoyant devices in the deep water. The exercises are summarized in Table 9.2.

Trunk-Strengthening Exercises: Standing

- Have the patient hold a kickboard vertically in the water to increase resistance while walking in various patterns.
- Have the patient use unilateral or bilateral stance while performing upper extremity motions. The buoyant and turbulent forces of the water require co-contraction of the trunk muscles to stabilize the immersed body. Use equipment (Hydro-tone® bells, paddles, resistive tubing) to increase resistance and the need for co-contraction of the trunk muscles.

Trunk-Strengthening Exercises: Semi-Reclined

Patients may use noodles, dumbbells, or kickboards for support. The practitioner can further challenge the patient by having him or her hold buoyant equipment, such as paddles, and then stabilize the trunk against the movement. A variety of lower extremity movements are suggested in Table 9.2.

Trunk-Strengthening Exercises: Supine

Various swimming kicks are used in the supine position. Instruct the patient to concentrate on the drawing-in maneuver and on maintaining the neutral spine position while moving the legs. Bridging while maintaining a neutral spine can be done with a long dumbbell placed at the knees.

Trunk-Strengthening Exercises: Prone

In the prone position, various swimming kicks, such as the flutter kick, are used while the patient performs the drawing-in maneuver and maintains a neutral spine.

Trunk-Strengthening Exercises in Deep Water

Stabilization exercises performed in deep water with the patient positioned vertically typically require the patient to brace with the abdominal muscles.[21,71,81] Emphasize identifying the neutral spine, activating the drawing-in maneuver, and holding the spine in the stable position while performing the various activities. Utilize any combination of unilateral or bilateral upper and/or lower extremity motions to further challenge the stabilization effort. Add equipment devices to the hands or legs for additional resistance and increased challenge when the patient can maintain good stabilization control. Variations include:

- Altering trunk positions such as the pike position or the iron-cross position.
- Sitting on a dumbbell and bicycling forward or backward or moving the upper extremities through any combination of motions.
- Standing on a kickboard or dumbbell and moving the upper extremities through various combinations of motions, first without then with equipment. Such standing activities typically induce obligatory abdominal bracing and challenges to balance.

TABLE 9.2 Summary of Lumbar Spine-Strengthening Exercises

Standing	Walking patterns: forward, backward, lateral, lunge walk, high stepping
	Unilateral/bilateral stance with upper extremity motions
Semi-reclined	Bicycling
	Hip abduction/adduction
	Flutter kick
	Bilateral lower extremity PNF patterns
	Unilateral/bilateral hip and knee flexion/extension
Supine	Bridging with long dumbbell placed at knees
	Swimming kicks
Prone	Swimming kicks
Deep water	Vertical stabilization exercises; abdominal bracing with arm and leg motions in the pike and iron-cross positions
	Seated on dumbbell; abdominal bracing and balance while performing unilateral or bilateral arm motions
	Standing on a kickboard or dumbbell; abdominal bracing and balance while performing bicycling motions and/or arm motions

Aerobic Conditioning

Aquatic exercise that emphasizes aerobic/cardiovascular conditioning can be an integral component of many rehabilitation programs.[59,82] Aerobic/cardiovascular exercise

typically takes place with the patient suspended vertically in deep water pools without the feet touching the pool bottom. Alternative activities that may be performed in mid-level water, 4 to 6 feet in depth, include jogging, swimming strokes, immersed cycling, and immersed treadmill. Understanding the various treatment options, physiological responses, monitoring methods, proper form, and equipment selection allows the clinician to use this form of exercise effectively and safely in a rehabilitation program.

Treatment Interventions

Deep-water walking/running (Fig. 9.25). Deep water walking and running are the most common vertical deep-water cardiovascular endurance exercises. Alternatives include cross-country motions and high-knee marching. Deep-water cardiovascular training, which may be used as a precursor to mid-water or land-based cardiovascular training, eliminates the effects of impact on the lower extremities and spine.

FIGURE 9.25 Deep water walking/jogging. *(Courtesy of Rothhammer International Inc. San Luis Obispo, CA.)*

The patient can be tethered to the edge of the pool to perform deep-water running in those pools with limited space. Some small tanks provide resistance jets for the patient to move against.

Mid-water jogging/running (immersed treadmill running). Mid-water aerobic exercise, which may be used as a precursor to land training, lessens the effects of impact on the spine and lower extremities. As a patient's tolerance to impact improves, mid-water jogging may be performed in progressively shallower depths to provide increased weight bearing and functional replication. In pools with limited space, tethering with resistive tubing can provide resistance.

Immersed equipment. Immersed equipment includes an immersed cycle, treadmill, or upper body ergometer.

Swimming strokes. For patients able to tolerate the positions necessary to perform various swim strokes (neck and shoulder ROM and prone, supine, or side-lying positions), swimming can be an excellent tool to train and improve cardiovascular fitness. Swimming may elicit significantly higher elevations of heart rate, blood pressure, and VO_{2max} than other aquatic activities. Swimming contributes the added benefit of hip and trunk strengthening for some patients with spinal conditions.

PRECAUTION: Recommending swimming for poorly skilled swimmers with cardiac compromise may adversely challenge the patient's cardiovascular system.

Physiological Response to Deep-Water Walking/Running

Various physiological responses to deep-water walking and running have been reported.[1,13,23,33,34,65]

Cardiovascular response. Patients without cardiovascular compromise may experience dampened elevation of heart rate, ventilation, and VO_{2max} compared to similar land-based exercise. During low-intensity exercise, cardiac patients may experience lower cardiovascular stresses.[54] As exercise intensity increases, cardiovascular stresses approach those of related exercise on land.[4,78]

Training effect. Patients experience carryover gains in VO_{2max} from aquatic to land conditions.[45] Additionally, aquatic cardiovascular training maintains leg strength and maximum oxygen consumption in healthy runners.[33,34,49,76]

Proper Form for Deep-Water Running

Instruction for beginners. Proper instruction is important to ensure correct form because many beginners experience a significant learning curve.[9] Once immersed, the patient should maintain a neutral cervical spine and slightly forward flexed trunk with the arms at the sides. During running the hips should alternately flex to approximately 80° with the knee extended and then extend to neutral as the knee flexes.

Accommodating specific patient populations. For patients with positional pain associated with spinal conditions, a posterior buoyancy belt helps maintain a slightly forward flexed position, and a flotation vest helps maintain more erect posture and a relatively extended spine. Patients with unilateral lower extremity amputations may have difficulty maintaining a vertical position. Placing the buoyancy belt laterally (on the contralateral side of the amputation) allows the patient to remain vertical more easily.

Exercise Monitoring

Monitoring intensity of exercise. Monitor the rate of perceived exertion and heart rate.

- *Rate of perceived exertion.* Because skill may affect technique, subjective numerical scales depicting perceived effort may inadequately identify the level of intensity for novice deep-water runners. However, at both submaximal and maximal levels of exertion, subjective numerical rating of effort appears to correlate adequately with the heart rate during immersed exercise.[33]
- *Heart rate.* Because of the physiological changes that occur with neck level immersion, various adjustments have been suggested in the literature to lower the immersed maximum heart rate during near-maximum cardiovascular exercise.[1,13,23,65,76] The suggested decreases range from 7 to 20 beats per minute.[1,13,23,65,76] The immersed heart rate can be reliably monitored manually or with water-resistant electronic monitoring devices.

Monitoring beginners. Care should be taken to monitor regularly the cardiovascular response of novice deep-water runners or patients with known cardiac, pulmonary, or peripheral vascular disease.[55] Novice deep-water runners may experience higher levels of perceived exertion and VO_{2max} than they would during similar land exercise.[23]

Equipment Selection

Deep water equipment. Selection of buoyancy devices should reflect the desired patient posture, comfort, and projected intensity level. The most common buoyant device for deep-water running is the flotation belt positioned posteriorly (see Fig. 9.7). Patients presenting with injuries or sensitivity of the trunk may require an alternative buoyant device, such as vests, flotation dumbbells, or noodles. Providing the patient with smaller buoyant equipment (i.e., smaller belts, fewer noodles) requires the patient to work harder to maintain adequate buoyancy, thereby increasing the intensity of the activity. Fins and specially designed boots can be applied to the legs and feet to add resistance. Also, bells or buoyant dumbbells can be held in the hands to increase resistance (see Fig. 9.10).

Midwater equipment. Specially designed socks can help eliminate the potential problem of skin breakdown on the feet during impact activities, such as running. Patients can run against a forced current or tethered with elastic tubing for resistance. Using noodles around the waist or running while holding a kickboard increases the amount of drag and resistance against which the patient must move.

Independent Learning Activities

Case Studies

Postoperative Arthroscopic Knee Meniscectomy

Mike is a 54-year-old man who tore his right medial meniscus playing basketball. He is 2 weeks status postarthroscopic débridement of the torn piece of cartilage. Mike has returned to his desk job as a computer programmer but has a strong desire to return to his active workout schedule and weekend sports leagues. The surgeon has told Mike that he has no limitations except pain.

Past Medical History: Mike is healthy with no prior medical problems. He has never had an injury that made him miss more than a few days of sports participation.

Functional Status: Mike is ambulating without assistive devices, but he limps slightly because of a stiff knee. He is able to go up and down stairs but only one step at a time and has to lead with his left leg.

Musculoskeletal Status: Mike has only minimal swelling of the right knee. He rates his pain as a 1 out of 10 at rest and a 3 out of 10 with activity. His active knee ROM is 5° to 100°. He has normal ROM in the remaining joints of the right leg. Mike is able to perform a straight leg raise and has good quadriceps contraction. Manual muscle testing reveals 4/5 quadriceps strength and 4/5 hamstring and gastrocsoleus strength. He has good patellofemoral joint mobility.

Physician Referral: The prescription Mike's physician gave him states, "Evaluate and treat right knee, S/P arthroscopic meniscal débridement; may utilize land and aquatic exercise for ROM and strength."

- Formalize a program to utilize the shallow water (4-ft depth) to start Mike with independent exercises for strength and flexibility.
- Describe what manual techniques you might be able to perform with Mike for strength or flexibility.
- As Mike progresses to full ROM and near-normal strength, how could you use aquatics to replicate the demands of basketball?
- What can Mike do in the pool to maintain his cardiovascular fitness while his knee heals?

Calf Tear

Cecily is a 30-year-old weather anchor who happens to be an elite marathon runner. Four days ago, she was running up a hill and felt a "pulling" in her left calf just distal to the knee. She decided to run in a 10K marathon the next day but had to quit after about 5K because of a sharp pain in her calf. The doctor has told her to use crutches and remain 25% weight-bearing for the next 3 days. After that she can gradually begin

to increase the weight she puts through the leg over the next week. The doctor has told Cecily that she should be full weight-bearing in 1 week and able to run in 3 weeks. Cecily is anxious to return to her intensive training schedule.

Past Medical History: Cecily is healthy with no prior medical problems. She has worn orthotic inserts in her shoes for "flat feet" for as long as she can remember. She says she has pulled her left calf several times during a running career that goes back to high school.

Functional Status: Cecily enters the facility ambulating with crutches. She is putting about 25% of her weight through her left foot. She is able to perform stairs without difficulty using the crutches and/or a railing.

Musculoskeletal Status: Cecily has a visible bruise at the medial head of the left gastrocnemius muscle belly. She is very tender to palpation there and has some swelling. She rates her pain at rest as 1 on a 10-point scale and her pain with activity as 2. Her ankle ROM is normal for all motions actively and passively with the exception of dorsiflexion. She dorsiflexes actively 5° and passively 8°. You grade her ankle strength as 5/5 except for plantarflexion, which you grade as a 4/5; this may be limited due to pain. You also notice that her left hip flexors, quadriceps, and hamstrings are all tight.

Physician Referral: The prescription that Cecily's doctor gives her states, "Aquatic therapy; evaluate and treat for left calf strain: gait training, ROM, strength. Progress to land as tolerated."

- Write up a program to address Cecily's dysfunctions and impairments utilizing the aquatic environment.
- At what depth of mid-water does Cecily need to be to gait train in the water and still maintain 25% weight-bearing?
- Write up a program for the deep water to help Cecily maintain her high level of cardiovascular fitness.
- What equipment might be useful to assist her with independent stretching in the deep water and for cardiovascular training in the deep water?

Chronic Low Back Pain

Develop an aquatic program for a patient who has chronic low back pain and needs a comprehensive flexibility and strengthening program for the legs and trunk. The patient has only one visit approved by the insurance company. However, the patient has a pool in his or her back yard that gradually goes from 3 feet to 7 feet in depth. The 7-foot deep area is only 10 feet long and 5 feet wide. The patient has no other medical problems that would limit his or her performance of the aquatic program.

CHAPTER 10

Soft Tissue Injury, Repair, and Management

The effective use of therapeutic exercise in the management of musculoskeletal disorders depends on sound clinical reasoning based on the best evidence available that supports the selection of the treatment interventions. Examination of the involved region is an important prerequisite for the structural and functional impairments that are limiting or may be preventing full participation in desired activities. It is also important during the examination process to determine whether the tissues involved are in the acute, subacute, or chronic stage of recovery so that the type and intensity of exercises do not interfere with recovery but can most effectively facilitate healing for maximum return of function and prevention of further problems. This chapter and subsequent chapters in this book have been written with the assumption that the reader has a foundation of knowledge and skills in examination, evaluation, and program planning for orthopedically related problems in order to make effective choices of exercises that will meet the goals.

Utilizing the principles presented in this chapter, the reader should be able to design therapeutic exercise programs and choose techniques for intervention that are at an appropriate intensity for the stage of healing of connective tissue disorders. Specific joint, soft tissue, boney, and nerve lesions as well as common surgical interventions are presented in the remaining chapters.

Soft Tissue Lesions

Examples of Soft Tissue Lesions: Musculoskeletal Disorders

- Strain: Overstretching, overexertion, overuse of soft tissue: tends to be less severe than a sprain, occurs from slight trauma or unaccustomed repeated trauma of a minor degree.[6] This term is frequently used to refer specifically to some degree of disruption of the musculotendinous unit.[14]
- Sprain: Severe stress, stretch, or tear of soft tissues, such as joint capsule, ligament, tendon, or muscle. This term is frequently used to refer specifically to injury of a ligament and is graded as first- (mild), second- (moderate), or third- (severe) degree sprain.[14]
- Dislocation: Displacement of a part, usually the boney partners in a joint, resulting in loss of the anatomical relationship and leading to soft tissue damage, inflammation, pain, and muscle spasm.
- Subluxation: An incomplete or partial dislocation of the boney partners in a joint that often involves secondary trauma to surrounding soft tissue.
- Muscle/tendon rupture or tear: If a rupture or tear is partial, pain is experienced in the region of the breach when the muscle is stretched or when it contracts against resistance.

If a rupture or tear is complete, the muscle does not pull against the injury, so stretching or contraction of the muscle does not cause pain.[8]

- Tendinopathy/tendinous lesions: *Tendinopathy* is the general term that refers to chronic tendon pathology.[23] *Tenosynovitis* is inflammation of the synovial membrane covering a tendon. *Tendinitis* is inflammation of a tendon; there may be resulting scarring or calcium deposits. *Tenovaginitis* is inflammation with thickening of a tendon sheath. *Tendinosis* is degeneration of the tendon due to repetitive microtrauma.
- Synovitis: Inflammation of a synovial membrane; an excess of normal synovial fluid in a joint or tendon sheath caused by trauma or disease.
- Hemarthrosis: Bleeding into a joint, usually due to severe trauma.
- Ganglion: Ballooning of the wall of a joint capsule or tendon sheath. Ganglia may arise after trauma, and they sometimes occur with rheumatoid arthritis.
- Bursitis: Inflammation of a bursa.
- Contusion: Bruising from a direct blow, resulting in capillary rupture, bleeding, edema, and an inflammatory response.
- Overuse syndromes, cumulative trauma disorders, repetitive strain injury: Repeated, submaximal overload and/or frictional wear to a muscle or tendon resulting in inflammation and pain.

Clinical Conditions Resulting from Trauma or Pathology

In many conditions involving soft tissue, the primary pathology is difficult to define or the tissue has healed with limitations, resulting in secondary loss of function. The following are examples of clinical manifestations resulting from a variety of causes, including those listed under the previous section.

- Dysfunction: Loss of normal function of a tissue or region. The dysfunction may be caused by adaptive shortening of the soft tissues, adhesions, muscle weakness, or any condition resulting in loss of normal mobility.
- Joint dysfunction: Mechanical loss of normal joint play in synovial joints; commonly causes loss of function and pain. Precipitating factors may be trauma, immobilization, disuse, aging, or a serious pathological condition.
- Contracture: Adaptive shortening of skin, fascia, muscle, or a joint capsule that prevents normal mobility or flexibility of that structure.
- Adhesion: Abnormal adherence of collagen fibers to surrounding structures during immobilization, after trauma, or as a complication of surgery, which restricts normal elasticity and gliding of the structures involved.
- Reflex muscle guarding: Prolonged contraction of a muscle in response to a painful stimulus. The primary pain-causing lesion may be in nearby or underlying tissue, or it may be a referred pain source. When not referred, the contracting muscle functionally splints the injured tissue against movement. Guarding ceases when the painful stimulus is relieved.
- Intrinsic muscle spasm: Prolonged contraction of a muscle in response to the local circulatory and metabolic changes that occur when a muscle is in a continued state of contraction. Pain is a result of the altered circulatory and metabolic environment, so the muscle contraction becomes self-perpetuating regardless of whether the primary lesion that caused the initial guarding is still irritable (Fig. 10.1). Spasm may also be a response of muscle to viral infection, cold, prolonged periods of immobilization, emotional tension, or direct trauma to muscle.

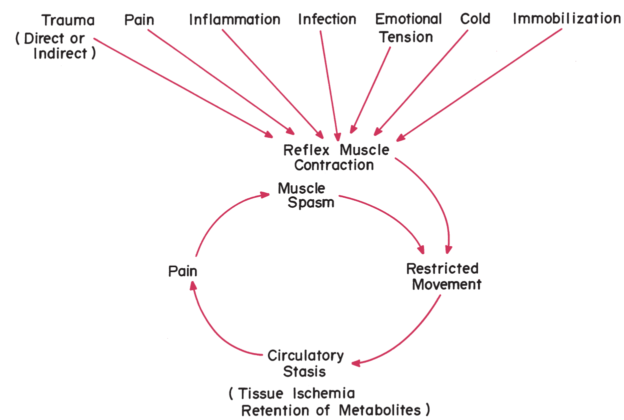

FIGURE 10.1 Self-perpetuating cycle of muscle spasm.

- Muscle weakness: A decrease in the strength of muscle contraction. Muscle weakness may be the result of a systemic, chemical, or local lesion of a nerve of the central or peripheral nervous system or the myoneural junction. It may also be the result of a direct insult to the muscle or simply due to inactivity.
- Myofascial compartment syndromes: Increased interstitial pressure in a closed, nonexpanding, myofascial compartment that compromises the function of the blood vessels, muscles, and nerves. It results in ischemia and irreversible muscle loss if there is no intervention.[4] Causes include, but are not limited to, fractures, repetitive trauma, crush injuries, skeletal traction, and restrictive clothing, wraps, or casts.

Severity of Tissue Injury

- *Grade 1 (first-degree).* Mild pain at the time of injury or within the first 24 hours. Mild swelling, local tenderness, and pain occur when the tissue is stressed.[14,15]
- *Grade 2 (second-degree).* Moderate pain that requires stopping the activity. Stress and palpation of the tissue greatly increase the pain. When the injury is to ligaments, some of the fibers are torn, resulting in some increased joint mobility.[14,15]
- *Grade 3 (third-degree).* Near-complete or complete tear or avulsion of the tissue (tendon or ligament) with severe

pain. Stress to the tissue is usually painless; palpation may reveal the defect. A torn ligament results in instability of the joint.[14,15]

Irritability of Tissue: Stages of Inflammation and Repair

After any insult to connective tissue, whether it is from mechanical injury (including surgery) or chemical irritant, the vascular and cellular response is similar (Table 10.1).[5] Tissue irritability, or sensitivity, is the result of these responses and is typically divided into three overlapping stages of inflammation, repair, and maturation/remodeling.[5,26,28] The following table summarizes the clinical signs and symptoms.

Acute Stage (Inflammatory Reaction)

During the acute stage, the signs of inflammation are present; they are swelling, redness, heat, pain at rest, and loss of function. When testing the range of motion (ROM), movement is painful, and the patient usually guards against the motion before completion of the range is possible (Fig. 10.2 A). The pain and impaired movement are from the altered chemical state that irritates the nerve endings, increased tissue tension due to edema or joint effusion, and muscle guarding, which is the body's way of immobilizing a painful area. This stage usually lasts 4 to 6 days unless the insult is perpetuated.

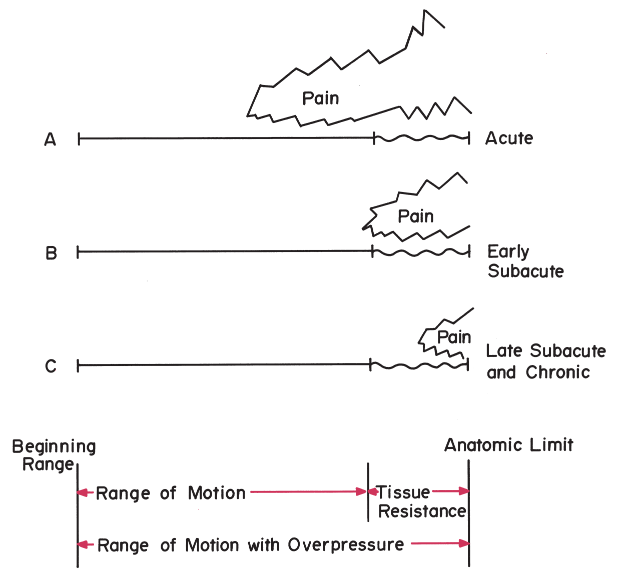

FIGURE 10.2 Pain experienced with ROM when involved tissue is in the **(A)** acute stage, **(B)** early subacute stage, and **(C)** late subacute or chronic stage.

Subacute Stage (Proliferation, Repair, and Healing)

During the subacute stage, the signs of inflammation progressively decrease and eventually are absent. When testing ROM, the patient may experience pain synchronous with encountering tissue resistance at the end of the available

TABLE 10.1 Stages of Tissue Healing: Characteristics, Clinical Signs, and Interventions

Acute Stage: Inflammatory Reaction	Subacute Stage: Proliferation, Repair and Healing	Chronic Stage: Maturation and Remodeling
Tissue responses and characteristics		
Vascular changes Exudation of cells and chemicals Clot formation Phagocytosis, neutralization of irritants Early fibroblastic activity	Removal of noxious stimuli Growth of capillary beds into area Collagen formation Granulation tissue Very fragile, easily injured tissue	Maturation of connective tissue Contracture of scar tissue Remodeling of scar Collagen aligns to stress
Clinical signs		
Inflammation Pain before tissue resistance	Decreasing inflammation Pain synchronous with tissue resistance	Absence of inflammation Pain after tissue resistance
Physical therapy goals and interventions for phases of rehabilitation		
Protection Phase: early	Controlled-Motion Phase: intermediate	Return to Function Phase: advanced
Control effects of inflammation: selective rest, ice, compression, elevation *Prevent deleterious effects of rest*: nondestructive movement: passive range of motion, massage, and muscle setting with caution	*Develop mobile scar:* selective stretching, mobilization/manipulation of restrictions *Promote healing:* nondestructive active, resistive, open- and closed-chain stabilization, muscular endurance, and cardiopulmonary endurance exercises, carefully progressed in intensity and range	*Increase tensile quality of scar:* progressive strengthening and endurance exercises *Develop functional independence:* functional exercises, and specificity drills

ROM (Fig. 10.2 B). Pain occurs only when the newly developing tissue is stressed beyond its tolerance or when tight tissue is stressed. Muscles may test weak, and function is limited as a result of the weakened tissue. This stage usually lasts 10 to 17 days (14 to 21 days after the onset of injury) but may last up to 6 weeks in some tissues with limited circulation, such as tendons.[10,26,28]

Chronic Stage (Maturation and Remodeling)

There are no signs of inflammation during the chronic stage. There may be contractures or adhesions that limit range, and there may be muscle weakness limiting normal function. During this stage, connective tissue continues to strengthen and remodel in response to the stresses applied to it.[9,23,26,28] A stretch pain may be felt when testing tight structures at the end of their available range (Fig. 10.2 C). Function may be limited by muscle weakness, poor endurance, or poor neuromuscular control. This stage may last 6 months to 1 year depending on the tissue involved and amount of tissue damage.

Chronic Inflammation

A state of prolonged inflammation may occur if injured tissue is continually stressed beyond its ability to repair. There are symptoms of increased pain, swelling, and muscle guarding that last more than several hours after activity. There are also increased feelings of stiffness after rest, loss of ROM 24 hours after activity, and progressively greater stiffness of the tissue as long as the irritation persists.

Chronic Pain Syndrome

Chronic pain syndrome is a state that persists longer than 6 months. It includes pain that cannot be linked to a source of irritation or inflammation and functional limitations and disability that include physical, emotional, and psychosocial parameters.

Management During the Acute Stage

Tissue Response: Inflammation

The inflammatory stage involves cellular, vascular, and chemical responses in the tissue. During the first 48 hours after insult to soft tissue, vascular changes predominate. Exudation of cells and solutes from the blood vessels takes place, and clot formation occurs. During this period, neutralization of the chemical irritants or noxious stimuli, phagocytosis (cleaning up of dead tissue), early fibroblastic activity, and formation of new capillary beds begin. These physiological processes serve as a protective mechanism as well as a stimulus for subsequent healing and repair.[5] Usually this stage lasts 4 to 6 days unless the insult is perpetuated.

Management Guidelines: Protection Phase

The therapist's role during the protection phase of intervention is to control the effects of the inflammation, facilitate wound healing, and maintain normal function in unaffected tissues and body regions. The information provided here is summarized in Box 10.1.

Patient Education

Inform the patient about the expected duration of symptoms (4 to 6 days), what he or she can do during this stage, any precautions or contraindications, and what to expect when the symptoms lessen. Patients need reassurance that the acute symptoms are usually short-lived, and they need to learn what is safe to do during this stage of healing.

Protection of the Injured Tissue

To minimize musculoskeletal pain and promote healing, protection of the part affected by the inflammatory process is necessary during the first 24 to 48 hours. This is usually provided by rest (splint, tape, cast), cold (ice), compression, and elevation. Depending on the type and severity of the injury, manual methods of pain and edema control, such as massage and gentle (grade I) joint oscillations, may be beneficial. If a lower extremity is involved, protection with assistive devices for partial or nonweight-bearing ambulation may be required.

Prevention of Adverse Effects of Immobility

Complete or continuous immobilization should be avoided whenever possible as it can lead to adherence of the developing fibrils to surrounding tissue, weakening of connective tissue, and changes in articular cartilage.[8,24,25]

A *long-term goal of treatment* is the formation of a strong, mobile scar at the site of the lesion, so there is complete and painless restoration of function. Initially, the network of fibril formation is random. It acquires an organized arrangement depending on the mechanical forces acting on the tissue.[16] To influence the development of an organized scar, begin treatment during the acute stage, when tolerated, with carefully controlled *passive movements.*

Tissue-specific movement. Tissue-specific movements should be directed to the structure involved to prevent abnormal adherence of the developing fibrils to surrounding tissue and thus avoid future disruption of the scar. Tissue-specific techniques are described below.

Intensity of movement. The intensity (dosage) of movement should be gentle enough so the fibrils are not detached from the site of healing. Too much movement too soon is painful and reinjures the tissue. The dosage of passive movement depends on the severity of the lesion. Some patients tolerate no movement during the first 24 to 48 hours; others tolerate only a few degrees of gentle passive movement. Continuous passive movement (CPM) (see Chapter 3) has been useful immediately after various types of surgery to joints—intra-articular, metaphyseal,

BOX 10.1 MANAGEMENT GUIDELINES—
Acute Stage/Protection Phase

Structural and Functional Impairments:

Inflammation, pain, edema, muscle spasm
Impaired movement
Joint effusion (if the joint is injured or if there is arthritis)
Decreased use of associated areas

Plan of Care	Intervention (up to 1 week postinjury)
1. Educate the patient.	1. Inform patient of anticipated recovery time and how to protect the part while maintaining appropriate functional activities.
2. Control pain, edema, spasm.	2. Cold, compression, elevation, massage (48 hours). Immobilize the part (rest, splint, tape, cast). Avoid positions of stress to the part. Gentle (grade I or II) joint oscillations with joint in pain-free position.
3. Maintain soft tissue and joint integrity and mobility.	3. Appropriate dosage of passive movements within limit of pain, specific to structure involved. Appropriate dosage of intermittent muscle setting or electrical stimulation.
4. Reduce joint swelling if symptoms are present.	4. May require medical intervention if swelling is rapid (blood). Provide protection (splint, cast).
5. Maintain integrity and function of associated areas.	5. Active-assistive, free, resistive, and/or modified aerobic exercises, depending on proximity to associated areas and effect on the primary lesion. Adaptive or assistive devices as needed to protect the part during functional activities.

PRECAUTIONS: The proper dosage of rest and movement must be used during the inflammatory stage. Signs of too much movement are increased pain or increased inflammation.

CONTRAINDICATIONS: Stretching and resistance exercises should not be performed at the site of the inflamed or swollen tissue.

and diaphyseal fractures; surgical release of extra-articular contractures and adhesions; and other select conditions.[24,25] Any movement tolerated at this stage is beneficial, but it must *not* increase the inflammation or pain. Active movement is usually *contraindicated* at the site of an active pathological process unless it is a chronic disease, such as rheumatoid arthritis.

General movement. Active movement is appropriate in neighboring regions to maintain integrity in uninjured tissue and to aid in circulation and lymphatic flow.

PRECAUTION: If movement increases pain or inflammation, it is either of too great a dosage or it should not be done. Extreme care must be used with movement at this stage.

Specific Interventions and Dosages

Passive range of motion. Passive range of motion (PROM) within the limit of pain is valuable for maintaining mobility in joints, ligaments, tendons, and muscles as well as improving fluid dynamics and maintaining nutrition in the joints.[24,25] Initially, the range is probably very small.[30] Stretching at this stage is contraindicated. Any motion gained from the PROM techniques is because of decreased pain, swelling, and muscle guarding.

Low-dosage joint mobilization/manipulation techniques. Grade I or II distraction and glide techniques have the benefit of improving fluid dynamics in the joint to maintain cartilage health. These techniques may also reflexively inhibit or gate the perception of pain. Low-dosage joint mobilizations are beneficial with joint pathologies and any other connective tissue injury that affects joint motion during the acute stage.

Muscle setting. Gentle isometric muscle contractions performed intermittently and at a very low-intensity so as not to cause pain or joint compression have several purposes. The pumping action of the contracting muscle assists the circulation and, therefore, fluid dynamics. If there is muscle damage or injury, the setting techniques are done with the muscle in the shortened position to help maintain mobility

of the actin-myosin filaments without stressing the breached tissue. If there is joint injury, the position during the setting techniques is dictated by pain; usually the resting position for the joint is most comfortable. If tolerated, the intermittent setting techniques are performed in several positions.

Massage. Massage serves the purpose of moving fluid, and if it is applied cautiously and gently to injured tissue, it may assist in preventing adhesions. Tendinous lesions are treated with a gentle dosage applied transverse to the fibers to smooth roughened surfaces or to maintain mobility of the tendon in its sheath. When applied, the tendon is kept taut. When treating muscle lesions, the muscle is usually kept in its shortened position so as not to separate the healing breach.[8] Massage to manage the effects of edema is discussed in Chapter 25.

Interventions for Associated Areas

During the protection phase, maintain as normal a physiological state as possible in related areas of the body. Include techniques to maintain or improve the following areas.

Range of motion. These techniques may be done actively or passively, depending on the proximity to and the effect on the injured tissue.

Resistance exercise. Resistance exercises may be applied at an appropriate dosage to muscles not directly related to the injured tissue to prepare the patient for use of assistive devices, such as crutches or a walker, and to improve functional activities.

Functional activities. Supportive or adaptive devices may be necessary depending on area of injury and expected functional activities.

CLINICAL TIP

It is important to prevent vascular stasis, which may occur due to swelling and immobility. Circulation is helped by encouraging functional activities within safe parameters and by using supportive elastic wraps, elevating the part, and using appropriate massage and muscle-setting techniques.

Management During the Subacute Stage

Tissue Response: Proliferation, Repair, and Healing

During the second to fourth days after tissue injury, the inflammation begins to decrease; the clot starts resolving; and repair of the injured site begins. This usually lasts an additional 10 to 17 days (14 to 21 days after the onset of injury) but may last up to 6 weeks.

The synthesis and deposition of collagen characterize this stage. Noxious stimuli are removed, and capillary beds begin to grow into the area. Fibroblastic activity, collagen formation, and granulation tissue development increase. Fibroblasts are present in tremendous numbers by the fourth day after injury and continue in large number until about day 21.[27] The fibroblasts produce new collagen, and this immature collagen replaces the exudate that originally formed the clot. In addition, myofibroblastic activity begins about day 5, causing scar shrinkage (contraction).[27,28] Depending on the size of injury, wound closure usually takes 5 to 8 days in muscle and skin and 3 to 6 weeks in tendons and ligaments.[10,28]

During this stage of healing, the immature connective tissue that is produced is thin and unorganized. It is extremely fragile and easily injured if overstressed, yet proper growth and alignment can be stimulated by appropriate tensile loading in the line of normal stresses for that tissue. At the same time, adherence to surrounding tissues can be minimized.[7]

Management Guidelines: Controlled Motion Phase

The therapist's role during this stage of healing is critical. The patient feels much better because the pain is no longer constant, and active movement can begin. It is easy to begin too much movement too soon or, conversely, to be tempted to approach intervention cautiously and not progress rapidly enough. Understanding the healing process and tissue response to stresses underlies the critical decisions that are made throughout this phase of intervention. The key is to initiate and progress *nondestructive* exercises and activities (i.e., exercises and activities that are within the tolerance of the healing tissues, which can then respond without re-injury or inflammation).[9] The information that follows is summarized in Box 10.2.

Patient Education

Inform the patient about what to expect at this stage, the time frame for healing, and what signs and symptoms indicate that he or she is pushing beyond tissue tolerance.

- Encourage the patient to return to normal activities that do not exacerbate symptoms, but caution against returning to recreational, sports, or work-related activities that would be detrimental to the healing process.
- Teach the patient a home exercise program and help him or her adapt work and recreational activities that are consistent with intervention strategies, so the patient becomes an active participant in the recovery process.

Management of Pain and Inflammation

Pain and inflammation decrease as healing progresses.

- Criteria for initiating active exercises and stretching during the early subacute stage include decreased swelling, pain that is no longer constant, and pain that is not exacerbated by motion in the available range.
- As new exercises are introduced or as the intensity of exercises is progressed, monitor the patient's response, so if symptoms warrant, the intensity of exercise can be modified.

BOX 10.2 MANAGEMENT GUIDELINES—
Subacute Stage/Controlled Motion Phase

Structural and Functional Impairments:

Pain when end of available ROM is reached
Edema (decreasing but may still be present)
Joint effusion (decreasing but may still be present if joints are involved)
Soft tissue, muscle, and/or joint contractures (developing in immobilized region)
Muscle weakness from reduced usage or pain
Decreased functional use of the part and associated areas

Plan of Care	Intervention (up to 3 weeks postinjury)
1. Educate the patient.	1. Inform patient of anticipated healing time and importance of following guidelines. Teach home exercises and encourage functional activities consistent with plan; monitor and modify as patient progresses.
2. Promote healing of injured tissues.	2. Monitor response of tissue to exercise progression; decrease intensity if pain or inflammation increases. Protect healing tissue with assistive devices, splints, tape, or wrap; progressively increase amount of time the joint is free to move each day and decrease use of assistive device as strength in supporting muscles increases.
3. Restore soft tissue, muscle, and/or joint mobility.	3. Progress from passive to active-assistive to active ROM within limits of pain. Gradually increase mobility of scar, specific to structure involved. Progressively increase mobility of related structures if limiting ROM; use techniques specific to tight structure.
4. Develop neuromuscular control, muscle endurance, and strength in involved and related muscles.	4. Initially, progress multiple-angle isometric exercises within patient's tolerance; begin cautiously with mild resistance. Initiate AROM, protected weight bearing, and stabilization exercises. As ROM, joint play, and healing improve, progress isotonic exercises with increased repetitions. Emphasize control of exercise pattern and proper mechanics. Progress resistance later in this stage.
5. Maintain integrity and function of associated areas.	5. Apply progressive strengthening and stabilizing exercises, monitoring effect on the primary lesion. Resume low-intensity functional activities involving the healing tissue that do not exacerbate the symptoms.

PRECAUTIONS: The signs of inflammation or joint swelling normally decrease early in this stage. Some discomfort will occur as the activity level is progressed, but it should not last longer than a couple of hours. Signs of too much motion or activity are resting pain, fatigue, increased weakness, and spasm lasting beyond 24 hours.

CLINICAL TIP

In the *subacute stage*, the new tissue is fragile and easily damaged. The patient often feels good and returns to normal activity too soon, causing exacerbation of symptoms.

- Exercises progressed too vigorously or functional activities begun too early can be injurious to the fragile, newly developing tissue and may delay recovery, cause pain, and perpetuate the inflammatory response.[9,27]
- Introduce and progress nondestructive movement at a safe intensity, so the new collagen fibers organize in response to stress and do not adhere to surrounding structures, becoming a future source of pain and limited tissue mobility.

Initiation of Active Exercises

Because of the restricted use of the injured region, there is muscle weakness even in the absence of muscle pathology. The subacute stage of healing is a transition period during which active exercises within the pain-free range of the injured tissue can begin and be progressed to muscular endurance and strengthening exercises with care, keeping within the tolerance

of the healing tissues (nondestructive motion). If activity is kept within a safe intensity and frequency, symptoms of pain and swelling progressively decrease each day. Patient response is the best guide to how quickly or vigorously to progress. Clinically, if signs of inflammation increase or the ROM progressively decreases, the intensity of the exercise and activity must decrease, because chronic inflammation has developed and a retracting scar will become more limiting.[2,3,17] Signs of excessive stress with exercise or activities are highlighted in Box 10.3.

Multiple-angle, submaximal isometric exercises. Submaximal isometric exercises are used during the early subacute stage to initiate control and strengthening of the muscles in the involved region in a nonstressful manner. They may also help the patient become aware of using the correct muscles. The intensity and angles for resistance are determined by the absence of pain.

- To initiate isometric exercise in an injured, healing muscle, place it in the shortened or relaxed position so the new scar is not pulled from the breached site.[7,27]
- To initiate isometric exercises when there is joint pathology, the resting position for the joint may be the most comfortable position. The intensity of contraction should be kept below the perception of pain.

Active range of motion exercises. Active range of motion (AROM) activities in pain-free ranges are used to develop control of the motion.

- Initially, use isolated, single plane motions. Emphasize control of the motion using light-resistive, concentric exercises of involved muscle and muscles needed for proper joint mechanics.
- Use combined motions or diagonal patterns to facilitate contraction of the desired muscles, but do not use patterns of motion that are dominated by stronger muscles with the weaker muscles not effectively participating at this early stage. Do not stress beyond the ability of the involved or weakened muscles to participate in the motion.

BOX 10.3 Signs of Excessive Stress with Exercise or Activities

- Exercise or activity soreness that does not decrease after 4 hours and is not resolved after 24 hours
- Exercise or activity pain that comes on earlier or is increased over the previous session
- Progressively increased feelings of stiffness and decreased ROM over several exercise sessions
- Swelling, redness, and warmth in the healing tissue
- Progressive weakness over several exercise sessions
- Decreased functional usage of the involved part

Exercise progressions may cause some temporary soreness that can last 4 hours, but if the above signs and symptoms occur, the activity, exercise, or stretching maneuvers are too stressful and should be modified or reduced in intensity.

Muscular endurance exercises. Exercises for muscle endurance are emphasized during the subacute phase, because slow-twitch muscle fibers are the first to atrophy when there is joint swelling, trauma, or immobilization.

- Initially, use only active ROM, with emphasis on control. Later during the healing phase, low-intensity, high-repetition exercise with light resistance is used rather than high-intensity resistance.
- Be certain that the patient is using correct movement patterns without substitution and is informed of the importance of stopping the exercise or activity when the involved muscle fatigues or involved tissue develops symptoms. For example, if the patient is doing shoulder flexion or abduction activities, substitution with scapular elevation should be avoided, or if the patient is doing leg-lift exercises, proper stabilization of the pelvis and the spine is important to ensure safety and correct motor learning.

Protected weight-bearing exercises. Partial weight bearing within the tolerance of the healing tissues may be used early to load the region in a controlled manner and stimulate stabilizing co-contractions in the muscles.

- Provide reinforcement to help develop awareness of appropriate muscle contractions and to help develop control while the patient shifts his or her weight in a side-to-side or anterior-to-posterior motion. As tolerated by the patient, progress by increasing the amplitude of movement or by decreasing the amount of support or protection.
- Add resistance to progress strength in the weight-bearing and stabilizing muscles.

PRECAUTION: Eccentric and heavy-resistance exercises (such as PRE) may cause added trauma to muscle and are not used in the early subacute stage after muscle injury when the weak tensile quality of the healing tissue could be jeopardized.[18] For nonmuscular injuries, eccentric exercises may not reinjure the part, but the resistance should be limited to a low-intensity at this stage to avoid delayed-onset muscle soreness. (This is in contrast to using eccentric exercises to facilitate and strengthen weak muscles when there has been no injury to take advantage of greater tension development with less energy in eccentric contractions, which is described in Chapter 6.)

Initiation and Progression of Stretching

Restricted motion during the acute stage and adherence of the developing scar usually cause decreased flexibility in the healing tissue and related structures in the region. To increase mobility and stimulate proper alignment of the developing scar, initiate stretching techniques that are specific to the tissues involved. More than one technique may have to be used to regain the ROM.

Warm the tissues. Use modalities or active ROM to increase the tissue temperature and relax the muscles for ease in stretching.

Muscle relaxation techniques. Muscles that are not relaxed interfere with joint mobilization and passive stretching of

inert tissue. If necessary, utilize hold-relax techniques first to be able to take the tissues to the end of their available range.

Joint mobilization/manipulation. If there is decreased joint play restricting range, it is important to begin stretching with specific joint techniques. Use grade III sustained or grade III and IV oscillation techniques to restore some of the joint slide prior to physiological stretching so as to minimize excessive compression of vulnerable cartilage. Joint distraction and gliding techniques are applied to stretch restricting capsular tissue (see Chapter 5 for the principles and techniques of joint mobilization).

Stretching techniques. Passive stretching techniques, self-stretching, and prolonged mechanical stretching are used to increase the extensibility of inert connective tissue, which permeates every structure in the body. These techniques are interspersed with neuromuscular inhibition techniques to relax and elongate the muscles crossing the joints (see Chapter 4 for the principles and techniques of stretching).

Massage. Various types of massage can be used for their soft tissue mobilizing effects. For example, cross-fiber friction massage is used to mobilize ligaments and incision sites so they move freely across the joint. Cross-fiber massage is also used at the site of muscle scar tissue or tendon adhesions to gain mobility of the scar tissue. The intensity and duration of the technique is progressively increased as the tissue responds.

Use of the new range. The patient must use the new range to maintain any extensibility gained with the stretching maneuvers and to develop control of the new range. Teach home exercises that include light resistance using the agonist in the new range as well as self-stretching techniques. Also help the patient incorporate the new range into his or her daily activities.

Correction of Contributing Factors

Continue to maintain or develop as normal a physiological and functional state as possible in related areas of the body. Address any postural or biomechanical impairments in stability, length, or strength that may have precipitated the problem or that may prevent full recovery. Resume low-intensity functional activities as the patient tolerates without exacerbating symptoms. Continue to reassess the patient's progress and understanding of the controlled activities.

Management During the Chronic Stage

Tissue Response: Maturation and Remodeling

Scar retraction from activity of the myofibroblasts is usually complete by the 21st day and the scar stops increasing in size, so from day 21 to day 60, there is a predominance of fibroblasts that are easily remodeled.[27] The process of maturation begins during the late subacute stage and continues for several months. The maturation and remodeling of the scar tissue occurs as collagen fibers become thicker and reorient in response to stresses placed on the connective tissue. Remodeling time is influenced by factors that affect the density and activity level of the fibroblasts, including the amount of time immobilized, stress placed on the tissue, location of the lesion, and vascular supply.

Maturation of Tissue

The primary differences in the state of the healing tissue between the late subacute and chronic stages are the improvement in quality (orientation and tensile strength) of the collagen and the reduction of the wound size during the chronic stages. The quantity of collagen stabilizes, and there is a balance between synthesis and degradation. Depending on the size of the structure or degree of injury or pathology, healing with progressively increasing tensile quality in the injured tissue may continue for 12 to 18 months.[10,19,27]

Remodeling of Tissue

Because of the way immature collagen molecules are held together (hydrogen bonding) and adhere to surrounding tissue, they can be easily remodeled with gentle and persistent treatment. This is possible for up to 10 weeks. If not properly stressed, the fibers adhere to surrounding tissue and form a restricting scar. As the structure of collagen changes to covalent bonding and thickens, it becomes stronger and resistant to remodeling. At 14 weeks, the scar tissue is unresponsive to remodeling. Consequently, an old scar has a poor response to stretch.[7] Treatment under these conditions requires either adaptive lengthening in the tissue surrounding the scar or surgical release.

Management Guidelines: Return to Function Phase

The therapist's role during this phase is to design a progression of exercises that safely stresses the maturing connective tissue in terms of both flexibility and strength, so the patient can return to his or her functional and work-related activities. Individuals returning to high-intensity activities require more intense exercises to prepare the tissues to withstand the stresses and train the neuromuscular system to respond to the demands of the activity.

Because remodeling of the maturing collagen occurs in response to the stresses placed on it, it is important to use controlled forces that replicate normal stresses on the tissue.[9,16,23] Maximum strength of the collagen develops in the direction of the imposed forces. Pain that the patient now experiences arises only when stress is placed on restrictive contractures or adhesions or when there is soreness due to increased stress of resistive exercise. To avoid chronic or recurring pain, the contractures must be stretched or the adhesions broken up and mobilized. Excessive or abnormal stress leads to reinjury and chronic inflammation, which can be detrimental to the return of function. The information that follows is summarized in Box 10.4.

BOX 10.4 MANAGEMENT GUIDELINES— Chronic Stage/Return to Function Phase

Structural and Functional Impairments:

Soft tissue and/or joint contractures and adhesions that limit normal ROM or joint play
Decreased muscle performance—weakness, poor endurance, poor neuromuscular control
Decreased functional usage of the involved part
Inability to function normally in an expected activity

Plan of Care	Interventions (>3 weeks post-injury)
1. Educate the patient.	1. Instruct patient in safe progressions of exercises and stretching. Monitor understanding and compliance. Teach ways to avoid reinjuring the part. Teach safe body mechanics. Provide ergonomic counseling.
2. Increase soft tissue, muscle and/or joint mobility.	2. Stretching techniques specific to tight tissue: ■ Joint and selected ligaments (joint mobilization/manipulation) ■ Ligaments, tendons, and soft tissue adhesions (cross-fiber massage) ■ Muscles (neuromuscular inhibition, passive stretch, massage, and flexibility exercises)
3. Improve neuromuscular *control,* strength, muscle endurance.	3. Progress exercises: ■ Submaximal to maximal resistance ■ Specificity of exercise using resisted concentric and eccentric, weight bearing and nonweight-bearing ■ Single plane to multiplanar motions ■ Simple to complex motions, emphasizing movements that simulate functional activities ■ Controlled proximal stability, superimpose distal motion ■ Safe biomechanics ■ Low repetitions to high repetitions at slow speeds; progress complexity and time; progress speed and time.
4. Improve cardiopulmonary endurance.	4. Progress aerobic exercises using safe activities.
5. Progress functional activities.	5. Continue using supportive and/or assistive devices until the ROM is functional with joint play, and strength in supporting muscles is adequate. Progress functional training with simulated activities from protected and controlled to unprotected and variable. Continue progressive strengthening exercises and advanced training activities until the muscles are strong enough and able to respond to the required functional demands.

PRECAUTIONS*:* There should be no signs of inflammation. Some discomfort will occur as the activity level is progressed, but it should not last longer than a couple of hours. Signs that activities are progressing too quickly or with too great a dosage are joint swelling, pain that lasts longer than 4 hours or that requires medication for relief, a decrease in strength, or fatiguing more easily.

Patient Education

Unless there is restrictive scar tissue requiring manual techniques for intervention, the patient becomes more responsible for carrying out the exercises in the plan of treatment.

- Instruct the patient in biomechanically safe progressions of resistance and self-stretching and how to self-monitor for detrimental effects and signs of excessive stress (see Box 10.3).
- Establish guidelines for what must be attained to return safely to recreational, sport, or work-related activities.
- Re-examine and evaluate the patient's progress and modify the exercises as progress is noted or if problems develop.

- Recommend modifications in daily living, work, or sport activities if they are contributing to the patient's impairments and preventing return to desired activities.

Considerations for Progression of Exercises

Free joint play within a useful (or functional) ROM is necessary to avoid joint trauma. If joint play is restricted, joint-mobilization/manipulation techniques should be used. These stretching techniques can be vigorous so long as no signs of increased irritation result.

Adequate muscle support is necessary to protect the joint. If there is weakness, faulty neuromuscular patterns may develop as functional activities are attempted. Poor support or faulty patterns of movement may result in microtrauma. The criterion for strength should be a muscle test grade of 4 on a 5-point scale in lower extremity musculature before discontinuing use of supportive or assistive devices for ambulation.

- To increase strength when there is a loss of joint play, use multiple-angle isometric exercises in the available range.
- Once joint play within the available ROM is restored, use resistive dynamic exercises within the available range. This does not imply that normal ROM needs to be present before initiating dynamic exercises but that joint play within the available range should be present (see Chapter 5 for information on joint play).
- In summary, joint dynamics and muscle strength and flexibility should be balanced as the injured part is progressed to functional exercises.

Progression of Stretching

Stretching of any restricting contractures or adhesions should be specific to the tissue involved using manual techniques, such as joint mobilization/manipulation, myofascial massage, PNF stretching, and passive stretching in addition to instruction in self-stretching (see Chapters 4 and 5 and the self-stretching exercises described in Chapters 16 to 22). At this stage, progress the intensity and duration of the stretching maneuvers so long as no signs of increased irritation persist beyond 24 hours.

Progression of Exercises for Muscle Performance: Developing Neuromuscular Control, Strength, and Endurance

As the patient's tissues heal, not only does treatment progress to stimulate proper maturation and remodeling in the healing tissue, but emphasis is also placed on controlled progressive exercises designed to prepare the patient to meet the functional outcomes.

- If the patient is not using some of the muscles because of inhibition, weakness, or dominance of substitute patterns, isolate the desired muscle action or use unidirectional motions to develop awareness of muscle activity and control of the movement.
- Progress exercises from isolated, unidirectional, simple movements to complex patterns and multidirectional movements requiring coordination with all muscles functioning for the desired activity.[29]
- Progress strengthening exercises to simulate specific demands including both weight-bearing and nonweight-bearing (closed- and open-chain) and both eccentric and concentric contractions.[22]
- Progress trunk stabilization, postural control, and balance exercises and combine with extremity motions for effective total body movement patterns.[29]
- Teach safe body mechanics and have the patient practice activities that replicate his or her work environment.
- Often overlooked but of importance in preventing injury associated with fatigue is developing muscular endurance in the prime mover muscles and stabilizing muscles as well as cardiopulmonary endurance.

Return to High-Demand Activities

Patients who must return to activities with greater-than-normal demand, such as is required in sports participation and heavy work settings, are progressed further to more intense exercises including plyometrics, agility training, and skill development.

- Develop exercise drills that simulate the work[13] or sport[2,29] activities using a controlled environment with specific, progressive resistance and plyometric drills.
- As the patient demonstrates capabilities, increase the repetitions and speed of the movement.
- Progress by changing the environment and introducing surprise and uncontrolled events into the activity.[1,29]

The importance of proper education to teach a safe progression of exercises and how to avoid damaging stresses cannot be overemphasized. To return to the activity that caused the injury prior to regaining functional pain-free motion, strength, endurance, and skill to match the demands of the task would probably result in recurring injury and pain.

Cumulative Trauma: Chronic Recurring Pain

Tissue Response: Chronic Inflammation

When connective tissue is injured, it goes through a healing process of repair, which was described in the preceding sections. However, in connective tissue that is repetitively stressed beyond the ability to repair itself, the inflammatory process is perpetuated. Proliferation of fibroblasts with increased collagen production and degradation of mature collagen leads to a predominance of new, immature collagen. This has an overall weakening effect on the tissue. In addition, myofibroblastic activity continues, which may lead to progressive limitation of

motion.[27] Efforts to stretch the inflamed tissue perpetuate irritation and progressive limitation.

Causes of Chronic Inflammation

Prolonged or recurring pain and resulting limitations in activity and function occur as a result of stress being imposed on tissues that are unable to respond to the repetitive or excessive nature of the stress.

Overuse, cumulative trauma, repetitive strain. These are terms descriptive of the repetitive nature of the precipitating event.[11] Repetitive microtrauma or repeated strain overload over time results in structural weakening, or fatigue breakdown, of connective tissue, with collagen fiber cross-link breakdown and inflammation. Initially, the inflammatory response from the microtrauma is subthreshold but eventually builds to the point of perceived pain and resulting dysfunction.

Repetitive microtrauma to tendons may lead to tendon degeneration.[28] It has been reported that inflammation occurs in the early stages of tendinopathy, but when tendons become degenerative, inflammation largely disappears, leading some to state that this is not an inflammatory condition.[23,26,28] Histological findings in tendinopathy have shown a poor healing response with collagen degeneration, fiber thinning and disorientation, hypercellularity, and scattered vascular ingrowth.[26]

Trauma. Trauma that is followed by superimposed repetitive trauma results in a condition that never completely heals. This may be the result of too early return to high-demand functional activities before the original injury has properly healed. The continued reinjury leads to the symptoms of chronic inflammation and dysfunction.

Reinjury of an "old scar." Scar tissue is not as compliant as surrounding, undamaged tissue. If the scar adheres to the surrounding tissues or is not properly aligned to the stresses imposed on the tissue, there is an alteration in the force transmission and energy absorption. This region becomes more susceptible to injury with stresses that normal, healthy tissue could sustain.

Contractures or poor mobility. Faulty postural habits or prolonged immobility may lead to connective tissue contractures that become stressed with repeated or vigorous activity.

Contributing Factors

By the nature of the condition, there is usually some factor that perpetuates the problem. Not only should the tissue at fault and its stage of pathology be identified, but the *mechanical cause* of the repetitive trauma needs to be defined. Evaluate for faulty mechanics or faulty habits that may be sustaining the irritation. Possibilities include:

- *Imbalance between the length and strength of the muscles* around the joint, leading to faulty mechanics of joint motion or abnormal forces through the muscles.
- *Rapid or excessive repeated eccentric demand* placed on muscles not prepared to withstand the load, leading to tissue failure, particularly in the musculotendinous region.[18]
- *Muscle weakness* or an inability to respond to excessive strength demands that results in muscle fatigue with decreased contractility and shock-absorbing capabilities and increased stress to supporting tissues.[18]
- *Bone malalignment or weak structural support* that causes faulty joint mechanics of force transmission through the joints (poor joint stability as in a flat foot).[20]
- *Change in the usual intensity or demands* of an activity such as an increase or change in an exercise or a training routine or change in job demands.[18]
- *Returning to an activity too soon after an injury* when the muscle-tendon unit is weakened and not ready for the stress of the activity.[9,12]
- *Sustained awkward postures or motions*, placing parts of the body at a mechanical disadvantage, leading to postural fatigue or injury.
- *Environmental factors* such as a work station not ergonomically designed for the individual, excessive cold, continued vibration, or inappropriate weight-bearing surface (for standing, walking, or running), which may contribute to any of the previous factors.
- *Age-related factors* such that a person attempts activities that could be done when younger but his or her tissues are no longer in condition to withstand the sustained stress.[21]
- *Training errors,* such as using improper methods, intensity, amount or equipment, or the condition of the participant, which lead to abnormal stresses.[20]
- *A combination of several contributing factors* are frequently seen that cause the symptoms.

Management Guidelines: Chronic Inflammation

When the patient has symptoms and signs of chronic inflammation, it is imperative that treatment begins by controlling the inflammation—in other words, treat it as an acute condition. Once the inflammation is under control, treatment progresses to dealing with the impairments and functional limitations. Management guidelines are summarized in Box 10.5.

Chronic Inflammation: Acute Stage

When the inflammatory response is perpetuated because of continued tissue irritation, the inflammation must be controlled to avoid the negative effects of continued tissue breakdown and excessive scar formation.

- In addition to the use of modalities and resting the part, it is imperative to identify and then modify the mechanism of chronic irritation with appropriate biomechanical counseling. This requires cooperation from the patient. Describe to the patient how the tissue reacts and breaks down under continued inflammation and explain the strategy of intervention.

BOX 10.5 MANAGEMENT GUIDELINES—Chronic Inflammation/Cumulative Trauma Syndromes

Structural and Functional Impairments:

Pain in the involved tissue of varying degrees:

- Only after doing repetitive activities
- When doing repetitive activities as well as after
- When attempting to do activities; completion of demands prevented
- Continued and unremitting

Soft tissue, muscle, and/or joint contractures or adhesions that limit normal ROM or joint play

Connective tissue weakness in painful region

Muscle weakness and poor muscular endurance in postural or stabilizing muscles as well as primary muscle at fault

Imbalance in length and strength between antagonistic muscles; biomechanical dysfunction

Decreased functional use of the region

Faulty position or movement pattern perpetuating the problem

Plan of Care	Interventions During Chronic Inflammation
1. Educate the patient.	1. Counsel as to cause of chronic irritation and need to avoid stressing the part while inflamed. Adapt the environment to decrease tissue stress. Implement a home exercise program to reinforce therapeutic interventions.
2. Promote healing; decrease pain and inflammation.	2. Cold, compression, massage Rest to the part (stop mechanical stress, splint, tape, cast)
3. Maintain integrity and mobility of involved tissue.	3. Nonstressful passive movement, massage, and muscle setting within limits of pain
4. Develop support in related regions.	4. Posture training Stabilization exercises

Plan of Care	Interventions—Controlled Motion and Return to Function Phases
1. Educate the patient.	1. Ergonomic counseling in ways to prevent recurrence Home instruction in safe progression of stretching and strengthening exercises. Instruction on signs of too much stress (see Box 10.3)
2. Develop strong, mobile scar.	2. Friction massage Soft tissue mobilization
3. Develop a balance in length and strength of the muscles.	3. Correct cause of faulty muscle and joint mechanics with appropriately graded stretching and strengthening exercises.
4. Progress functional independence.	4. Train muscles to function according to demand; provide alternatives or support if they cannot. Train coordination and timing. Develop endurance.
5. Analyze job/activity.	5. Adapt home, work, and sport environment/tools.

PRECAUTION: If there is progressive loss of ROM as the result of stretching, do not continue to stretch. Reevaluate the condition and determine if there is still a chronic inflammation with contracting scar or if there is protective muscle guarding. Emphasize stabilizing the part and training in safe adaptive patterns of motion.

CLINICAL TIP

Use of illustrations to help the patient understand the mechanism of tissue breakdown with cumulative trauma syndromes—such as what happens when a person repeatedly hits a thumbnail with a hammer or repeatedly irritates or scrapes a skin area before it heals—helps the patient visualize the repeated trauma occurring in the musculoskeletal problem and understand the need to quit "hitting or irritating the sore."

- Initially, allow only nonstressful activities.
- Initiate exercises at safe, nonstressful intensities in the involved tissues, as with any acute lesion, and at appropriate corrective intensities in related regions without stressing the involved tissues.

Subacute and Chronic Stages of Healing Following Chronic Inflammation

Once the constant pain from the chronic inflammation has decreased, progress the patient through an exercise program with controlled stresses until the connective tissue in the involved region has developed the ability to withstand the stresses imposed by the functional activities.

- Locally, if there is a chronic, contracted scar that limits range or continually becomes irritated with microruptures, mobilize the scar in the tissue using friction massage, soft tissue manipulation, or stretching techniques. If inflammation results from the stretching maneuvers, treat it as an acute injury. Because chronic inflammation can lead to proliferation of scar tissue and contraction of the scar, progressive loss of range is a warning sign that the intensity of stretching is too vigorous.
- Muscle guarding could be a sign that the body is attempting to protect the part from excessive motion. In this case, the emphasis is on developing stabilization of the part and training in safe adaptive patterns of motion.
- Identify the cause of the faulty muscle and joint mechanics. Strengthening and stabilization exercises, in conjunction with working or recreational adaptations, are necessary to minimize the irritating patterns of motion.
- Because chronic irritation problems frequently result from an inability to sustain repetitive activities, muscle endurance is an appropriate component of the muscle re-education program. Consider endurance in the postural stabilizers as well as in the prime movers of the desired functional activity.
- As when treating patients in the chronic stage of healing, progress exercises to develop functional independence. The exercises become specific to the demand and include timing, coordination, and skill.
- Work-conditioning and work-hardening programs may be used to prepare the person for return to work; training in sports-specific exercises is important for returning an individual to sports.

NOTE: Specific overuse syndromes are covered in detail in the respective chapters associated with the involved region.

Independent Learning Activities

Critical Thinking and Discussion

1. Your patient has experienced an injury to a muscle. Describe the symptoms that he or she will experience during each stage of inflammation and repair, and describe the principles of the exercise intervention that should be used during each stage. Once you have identified the principles, choose a commonly injured muscle, such as the hamstrings, and describe the symptoms, test results, goals, treatment plan, and actual interventions that you would use for each stage of intervention.
2. Do the same activity as in #1 except use a ligamentous injury, such as strain of the humeroulnar ligament or anterior talofibular ligament.
3. Describe the mechanism of injury for common overuse syndromes, such as lateral epicondylitis or shin splints, and explain the differences between such an injury and an acute traumatic injury.

CHAPTER

11

Joint, Connective Tissue, and Bone Disorders and Management

CAROLYN KISNER, PT, MS ■ KAREN HOLTGREFE, PT, DHS, OCS

General guidelines and principles for developing exercise interventions for patients with soft tissue lesions were presented in the previous chapter. The purpose of this chapter is to present principles of management of selected pathologies that affect joints, connective tissue, and bone. Characteristics of arthritis, fibromyalgia, myofascial pain syndrome, osteoporosis, and fractures are described in conjunction with the effects of therapeutic exercise on impairments associated with these pathological conditions.

Arthritis: Arthrosis

Arthritis is inflammation of a joint. There are many types of arthritis, both inflammatory and noninflammatory, that affect joints and other connective tissues in the body. The most common types treated by therapists are rheumatoid arthritis and osteoarthritis. *Arthrosis* is limitation of a joint without inflammation. Unless the cause of the joint problems is known, such as recent trauma or immobility, medical intervention is necessary to diagnose and medically manage the pathology. Traumatic arthritis may require aspiration if there is bloody effusion. The therapist manages the impairments, activity limitations, and participation restrictions that result from the underlying pathology.

Clinical Signs and Symptoms

Signs and symptoms common to all types of arthritic conditions generally include the following.

Impaired Mobility

The patient usually presents with signs typical of joint involvement that include a characteristic pattern of limitation (called a capsular pattern), usually a firm end-feel (unless acute—then the end-feel may be guarded), decreased and possibly painful joint play, and joint swelling (effusion).[49] Additional signs and symptoms may be present depending on the specific disease process. Table 11.1 summarizes the characteristic signs and symptoms of osteoarthritis and rheumatoid arthritis.

Arthrosis may be present if the individual is recovering from a fracture or other problem requiring immobilization. There is limited joint play along with other connective tissue and muscular contractures limiting ROM.

Impaired Muscle Performance

Weakness from disuse or reflex inhibition of stabilizing muscles occur when there is joint swelling or pain. Muscle weakness or inhibition leads to imbalances in strength and flexibility and poor support for the involved joints. Asymmetry in muscle pull may be a deforming force to the joints, and poor muscle support allows the joint to be more susceptible to trauma; conversely, good muscle support helps protect an arthritic joint.

Impaired Balance

Patients may develop balance deficits because of altered or decreased sensory input from joint mechanoreceptors and muscle spindle. This is particularly a problem with weight-bearing joints.[96]

TABLE 11.1 Comparison of Osteoarthritis and Rheumatoid Arthritis[5,18,44,84,91,92]

Characteristics	Osteoarthritis	Rheumatoid Arthritis
Age of onset	Usually after age of 40	Usually begins between age 15 and 50
Progression	Usually develops slowly over many years in response to mechanical stress	May develop suddenly, within weeks or months
Manifestations	Cartilage degradation, altered joint architecture, osteophyte formation	Inflammatory synovitis and irreversible structural damage to cartilage and bone
Joint involvement	Affects a few joints (usually asymmetrical); typically: —DIP, PIP, 1st CMC of hands —Cervical and lumbar spine —Hips, knees, 1st MTP of feet	Usually affects many joints, usually bilateral; typically: —MCP and PIP of hands, wrists, elbows, shoulders —Cervical spine —MTP, talonavicular and ankle
Joint signs and symptoms	Morning stiffness (usually <30 min), increased joint pain with weight-bearing and strenuous activity; crepitus and loss of ROM	Redness, warmth, swelling, and prolonged morning stiffness; increased joint pain with activity
Systemic signs and symptoms	None	General feeling of sickness and fatigue, weight loss and fever; may develop rheumatoid nodules, may have ocular, respiratory, hematological, and cardiac symptoms

Activity Limitations and Participation Restrictions

The ability to carry out home, community, work-related, or social activities may be minimally to significantly restricted. Adaptive and assistive devices may be used by the patient to improve function or help prevent possible deforming forces. A variety of classification systems and functional instruments have been developed for use in clinical studies as well as routine practice to measure patient function and outcomes in response to interventions.[42]

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is an autoimmune, chronic, inflammatory, systemic disease primarily of unknown etiology affecting the synovial lining of joints as well as other connective tissue. It is characterized by a fluctuating course, with periods of active disease and remission. The onset and progression vary from mild joint symptoms with aching and stiffness to abrupt swelling, stiffness, and progressive deformity.[3,5,10,58,74] The criteria for classification of RA are summarized in Box 11.1.

Characteristics of RA

- Characterized by symmetric, errosive synovitis[3] with periods of exacerbation (flare) and remission.[5,10,58] Joints are characteristically involved with early inflammatory changes in the synovial membrane, peripheral portions of the articular cartilage, and subchondral marrow spaces. In response, granulation tissue (pannus) forms, covers, and erodes the articular cartilage, bone, and ligaments in the joint capsule. Adhesions may form, restricting joint mobility. With progression of the disease, cancellous bone becomes exposed. Fibrosis, ossific ankylosis, or subluxation may eventually cause deformity and disability (Figs. 11.1, 11.2, 11.3).[5,74]
- Inflammatory changes also occur in tendon sheaths (tenosynovitis); if subjected to recurring friction, the tendons may fray or rupture.

BOX 11.1 Criteria for Diagnosis of Rheumatoid Arthritis[6]

1. Morning stiffness in and around the joints, lasting at least 1 hour before maximal improvement
2. At least three of the following joints simultaneously have soft tissue swelling or fluid observed by a physician: right or left proximal interphalangeal (PIP); metacarpophalangeal (MCP); wrist, elbow, knee, ankle, and metatarsophalangeal (MTP) joints).
3. Swelling in the wrist, MCP, or PIP joints
4. Symmetrical joint involvement (bilateral involvement of PIP, MCP, or MTP joints may occur without absolute symmetry)
5. Rheumatoid nodules
6. Positive serum rheumatoid factor
7. Radiographic changes including erosions or or boney decalcification localized in or adjacent to the involved joints

NOTE: RA is defined by the presence of at least four of these seven criteria. Numbers 1–4 must have been present for at least 6 weeks.

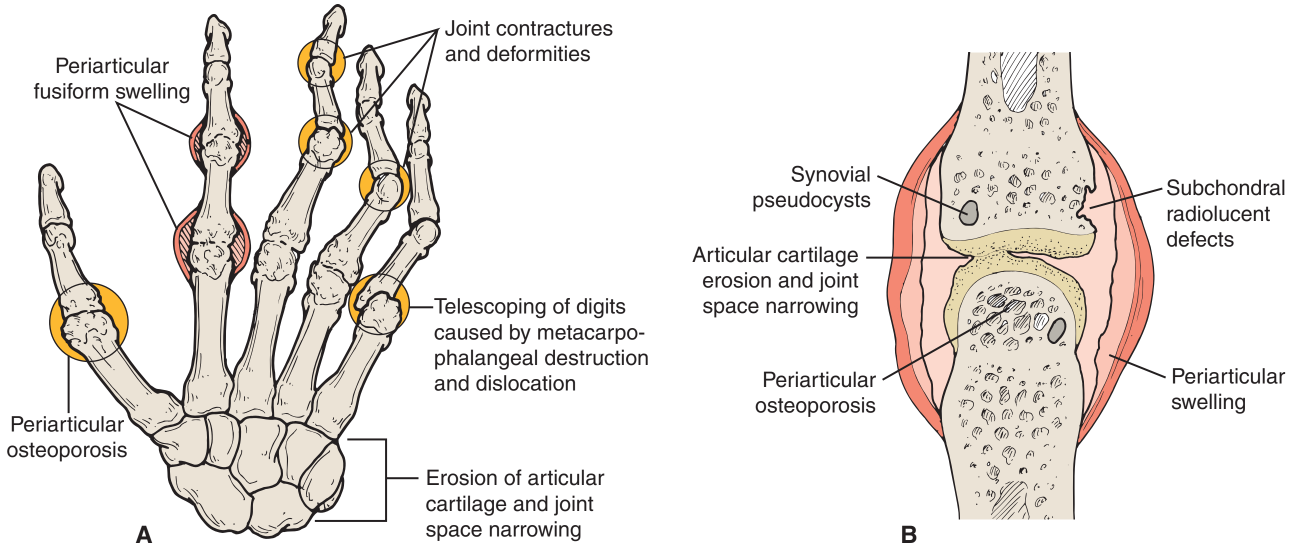

FIGURE 11.1 (A) Radiographic hallmarks and typical joint deformities with rheumatoid arthritis in small joints of the wrist and hand. **(B)** Radiographic hallmarks of rheumatoid arthritis in large joints.

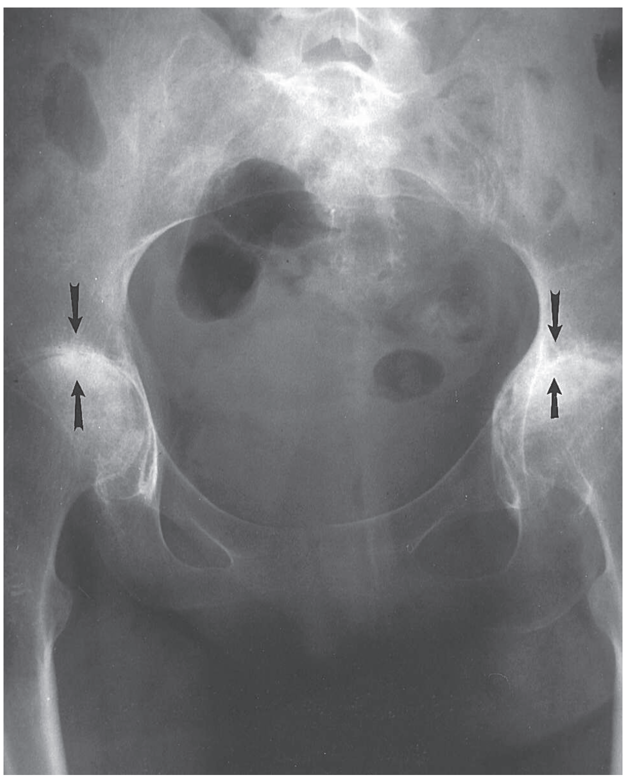

FIGURE 11.2 Advanced rheumatoid arthritis of the hip joints. Note that the destruction caused by rheumatoid arthritis involves the entire joint space and the boney regions on either side of the joint space. *(From McKinnis,[62] p 55, with permission.)*

FIGURE 11.3 Rheumatoid arthritis of the foot. First metatarsophalangeal joint shows severe *erosion* of the joint surface with *subluxation* of the metatarsal (arrow). *(From McKinnis,[62] p 58, with permission.)*

- Extra-articular pathological changes sometimes occur; they include rheumatoid nodules, atrophy and fibrosis of muscles with associated muscular weakness, fatigue, and mild cardiac changes.
- Progressive deterioration and decline in the functional level of the individual attributed to the muscular changes and progressive muscle weakness is often seen,[24] leading to major economic loss and significant impact on families.[3]
- The degree of involvement varies. Some individuals experience mild symptoms that require minor lifestyle changes and mild anti-inflammatory medications. Others experience significant pathological changes in the joints that require major adaptations in lifestyle. Loss of joint function is irreversible, and often surgery is needed to decrease pain

and improve function. Early recognition is essential during the initial stages, with referral to a rheumatologist for diagnosis and medical management to control the inflammation and minimize joint damage.[18]

Signs and Symptoms: Periods of Active Disease

- With synovial inflammation, there is effusion and swelling of the joints, which cause aching and limited motion. Joint stiffness is prominent in the morning. Usually there is pain on motion, and a slight increase in skin temperature can be detected over the joints. Pain and stiffness worsen after strenuous activity.
- Onset is usually in the smaller joints of the hands and feet, most commonly in the proximal interphalangeal joints. Usually symptoms are bilateral.
- With progression, the joints become deformed and may ankylose or subluxate.
- Pain is often felt in adjoining muscles, and eventually muscle atrophy and weakness occur. Asymmetry in muscle strength and alterations in the line of pull of muscles and tendons add to the deforming forces.
- The person often experiences nonspecific symptoms such as low-grade fever, loss of appetite and weight, malaise, and fatigue.

Principles of Management: Active Inflammatory Period of RA

Management guidelines are summarized in Box 11.2.

- *Patient Education.* Because periods of active disease may last several months to more than a year, begin education in the overall treatment plan, safe activity, and joint protection (Box 11.3) as soon as possible.[60] It is imperative to involve the patient in the management, so he or she learns

BOX 11.2 MANAGEMENT GUIDELINES—
Rheumatoid Arthritis/Active Disease Period

Structural/Functional Impairments, Activity Limitations, and Participation Restrictions:

Tenderness and warmth over the involved joints with joint swelling
Muscle guarding and pain on motion
Joint stiffness and limited motion
Muscle weakness and atrophy
Potential deformity and ankylosis from the degenerative process and asymmetric muscle pull
Fatigue, malaise, sleep disorders
Restricted ADLs and IADLs

Plan of Care	Interventions
1. Educate the patient.	1. Inform the patient on importance of rest, joint protection, energy conservation, and performance of ROM. Teach home exercise program and activity modifications that conserve energy and minimize stress to vulnerable joints.
2. Relieve pain and muscle guarding and promote relaxation.	2. Modalities Gentle massage Immobilize in splint Relaxation techniques Medications as prescribed by physician
3. Minimize joint stiffness and maintain available motion.	3. Passive or active-assistive ROM within limits of pain, gradual progression as tolerated. Gentle joint techniques using grade I or II oscillations.
4. Minimize muscle atrophy.	4. Gentle isometrics in pain-free positions, progression to ROM when tolerated.
5. Prevent deformity and protect the joint structures.	5. Use of supportive and assistive equipment for all pathologically active joints. Good bed positioning while resting. Avoidance of activities that stress the joints.

PRECAUTIONS: Respect fatigue and increased pain; do not overstress osteoporotic bone or lax ligaments.

CONTRAINDICATIONS: Do not stretch swollen joints or apply heavy resistance exercise that cause joint stress.

BOX 11.3 Principles of Joint Protection and Energy Conservation[53,73]

- Monitor activities and stop when discomfort or fatigue begins to develop.
- Use frequent but short episodes of exercise (three to five sessions per day) rather than one long session.
- Alternate activities to avoid fatigue.
- Decrease level of activities or omit provoking activities if joint pain develops and persists for more than 1 hour after activity.
- Maintain a functional level of joint ROM and muscular strength and endurance.
- Balance work and rest to avoid muscular and total body fatigue.
- Increase rest during flares of the disease.
- Avoid deforming positions.
- Avoid prolonged static positioning; change positions during the day every 20 to 30 minutes.
- Use stronger and larger muscles and joints during activities whenever possible.
- Use appropriate adaptive equipment.

how to conserve energy and avoid potential deforming stresses during activities and when exercising.

- *Joint protection and energy conservation.* It is important that the patient learns to respect fatigue and, when tired, rests to minimize undue stress to all the body systems. Because inflamed joints are easily damaged and rest is encouraged to protect the joints, teach the patient how to rest the joints in nondeforming positions and to intersperse rest with ROM.
- *Joint mobility*. Use gentle grade I and II distraction and oscillation techniques to inhibit pain and minimize fluid stasis. Stretching techniques are not performed when joints are swollen.
- *Exercise.* The type and intensity of exercise vary depending on the symptoms. Encourage the patient to do active exercises through as much ROM as possible (not stretching). If active exercises are not tolerated owing to pain and swelling, passive ROM is used. Once symptoms of pain and signs of swelling are controlled with medication, progress exercises as if subacute.

CLINICAL TIP

Therapeutic exercises cannot positively alter the pathological process of RA, but if administered carefully, they can help prevent, retard, or correct the mechanical limitations and deforming forces that occur and therefore, help maintain function.

- *Functional training.* Modify any activities of daily living (ADL) needed in order to protect the joints. If necessary, use splints and assistive devices to provide protection.

PRECAUTIONS: Secondary effects of steroidal medications may include osteoporosis and ligamentous laxity, so use exercises that do not cause excessive stress to bones or joints.

CONTRAINDICATIONS: Do not perform stretching techniques across swollen joints. When there is effusion, limited motion is the result of excessive fluid in the joint space. Forcing motion on the distended capsule overstretches it, leading to subsequent hypermobility (or subluxation) when the swelling abates. It may also increase the irritability of the joint and prolong the joint reaction.

Principles of Management: Subacute and Chronic Stages of RA

As the intensity of pain, joint swelling, morning stiffness, and systemic effects diminish, the disease is considered subacute. Often medications can decrease the acute symptoms, so the patient can function as if in the subacute stage. The chronic stage occurs between exacerbations. This may be very short in duration, or it may last many years.

- *Treatment approach.* The treatment approach is the same as with any subacute and chronic musculoskeletal disorder, except appropriate precautions must be taken because the pathological changes from the disease process make the tissues more susceptible to damage.
- *Joint protection and activity modification*. Continue to emphasize the importance of protecting the joints by modifying activity, using splints, asssistive devices, and environmental adaptations for safe function.
- *Flexibility and strength.* To improve function, exercises should be aimed at improving flexibility, muscle strength, and muscle endurance within the tolerance of the joints.[24]
- *Cardiopulmonary endurance.* Nonimpact or low-impact conditioning exercises—such as aquatic exercise, cycling, aerobic dancing, and walking/running—performed within the tolerance of the individual with RA, improve aerobic capacity and physical activity and decrease depression and anxiety.[8,64,99] Group activities, such as water aerobics, also provide social support in conjunction with the activity. One randomized review suggested that aerobic training also has a positive impact on the cardiovascular status of patients with RA.[63]

PRECAUTIONS: The joint capsule, ligaments, and tendons may be structurally weakened by the rheumatic process (also as a result of using steroids), so the dosage of stretching and joint mobilization techniques used to counter any contractures or adhesions must be carefully graded.

CONTRAINDICATIONS: Vigorous stretching or manipulative techniques.

FOCUS ON EVIDENCE

The results of a study[95] of patients with active but medically controlled RA demonstrated that subjects who participated

in a carefully supervised intensive exercise program showed greater improvement in function and muscle strength, a greater decrease in the number of clinically active joints, and a faster rate of diminished disease activity compared to the control group of patients who participated in a program of ROM and isometric exercise. The intensive exercises included isokinetic resistance to the knees at 70% maximum voluntary contraction and angular velocity at 60°/sec, isometric exercises at 70% maximum voluntary contraction, bicycling at 60% of the age-predicted maximum for 15 minutes, and ROM exercises. All exercises were adjusted to the pain tolerance of the individual when needed. The primary conclusion of this study was that there is no evidence that patients with active disease should be prevented from vigorous exercise so long as fatigue and pain are respected. The study did not look at joint erosion or cartilage damage.

Several systematic reviews looking at best evidence for the use of therapeutic exercise in the treatment of RA have been published.[14,23,27,63] Although there are few randomized well-controlled studies looking at the outcome of exercise, studies of various strength do support that therapeutic exercise, including functional strengthening and aerobic exercise, are beneficial for patients with RA demonstrating relief of pain, improved muscle strength, and functional status. In one of the reviews,[27] investigators found that moderate- or high-intensity exercise in patients with RA has a minimal effect on disease activity and radiological evidence of damage in the hands and feet, but that there is insufficient radiological evidence to determine the effect in large joints. The reviewers also reported that long-term moderate- or high-intensity exercises (individualized to protect radiologically damaged joints) improve aerobic capacity, muscle strength, functional ability, and psychological well-being in patients with RA.[27]

Osteoarthritis: Degenerative Joint Disease

Osteoarthritis (OA) is a chronic degenerative disorder primarily affecting the articular cartilage of synovial joints, with eventual boney remodeling and overgrowth at the margins of the joints (spurs and lipping) (Fig. 11.4). There is also progression of synovial and capsular thickening and joint effusion. The impairments from OA lead to activity limitations and participations restrictions in a substantial number of people with a significant social and financial impact as a result of surgical and medical interventions.[15]

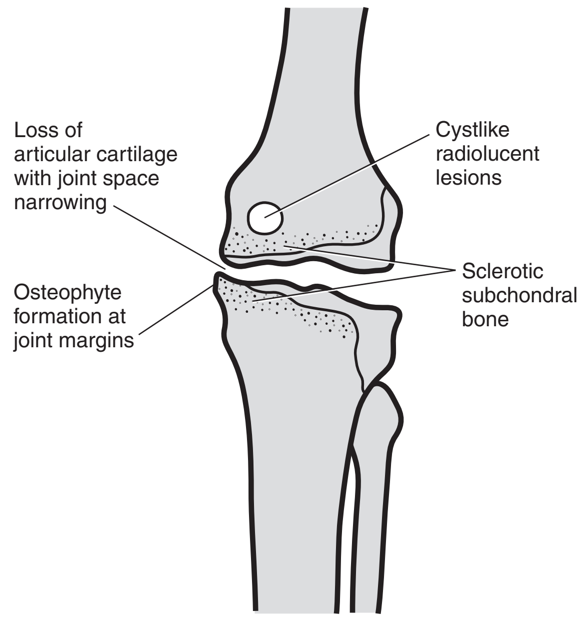

FIGURE 11.4 Radiographic hallmarks of osteoarthritis. *(From McKinnis,[62] p 61, with permission.)*

Characteristics of OA

- With degeneration, there may be capsular laxity as a result of bone remodeling and capsule distention, leading to hypermobility or instability in some ranges of joint motion. With pain and decreased willingness to move, contractures eventually develop in portions of the capsule and overlying muscle, so as the disease progresses, motion becomes more limited.[31,44]
- Although the etiology of OA is not known, mechanical injury to the joint due to a major stress or repeated minor stresses and poor movement of synovial fluid when the joint is immobilized are possible causes. Rapid destruction of articular cartilage occurs with immobilization, because the cartilage is not being bathed by moving synovial fluid and is thus deprived of its nutritional supply.[10]
- OA is also genetically related, especially in the hands and hips and to some degree in the knees.[31] Other risk factors that show a direct relationship to OA are obesity, weakness of the quadriceps muscles, joint impact, sports with repetitive impact and twisting (e.g., soccer, baseball pitching, football), and occupational activities such as jobs that require kneeling and squatting with heavy lifting.[31]
- The cartilage splits and thins out, losing its ability to withstand stress. As a result, crepitation or loose bodies may occur in the joint. Eventually, subchondral bone

becomes exposed. There is increased density of the bone along the joint line, with cystic bone loss and osteoporosis in the adjacent metaphysis. During the early stages, the joint is usually asymptomatic because the cartilage is avascular and aneural, but pain becomes constant in later stages.

- Affected joints may become enlarged. Heberden's nodes (enlargement of the distal interphalangeal joints of the fingers) and Bouchard's nodes (enlargement of the proximal interphalangeal joints) are common.
- Most commonly involved are weight-bearing joints (hips and knees), the cervical and lumbar spine, and the distal interphalangeal joints of the fingers and carpometacarpal joints of the thumbs (Figs. 11.5 and 11.6).

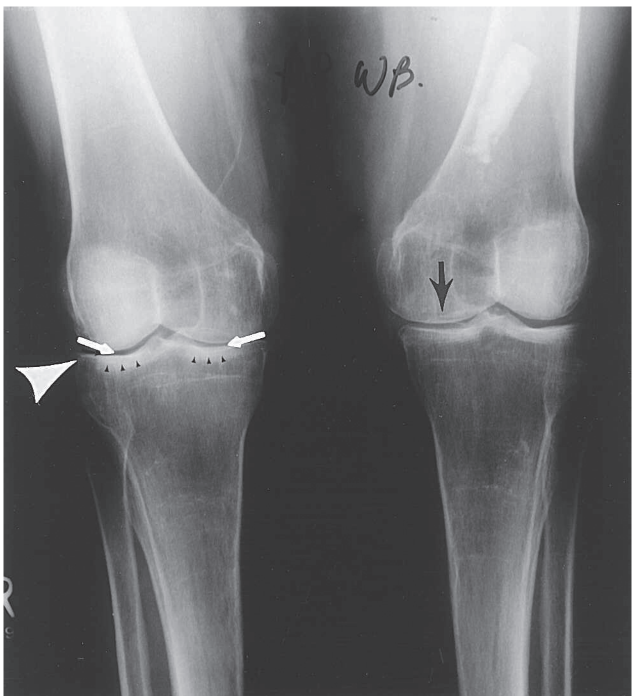

FIGURE 11.5 Osteoarthritis of the knees in a 66-year-old woman. This film was taken under weight-bearing conditions. At the patient's right knee, osteoarthritis is evidenced by narrowed joint space (white arrows), osteophyte formation at the joint margins (large white arrowhead), and sclerotic subchondral bone (small black arrowheads) of both the medial and lateral tibial plateaus. At the patient's left knee, it is interesting to note that in the area of minimal weight-bearing stress the subchondral bone has lost density, and rarefaction is present on the medial aspect of the joint. *(From McKinnis,[62] p 62, with permission.)*

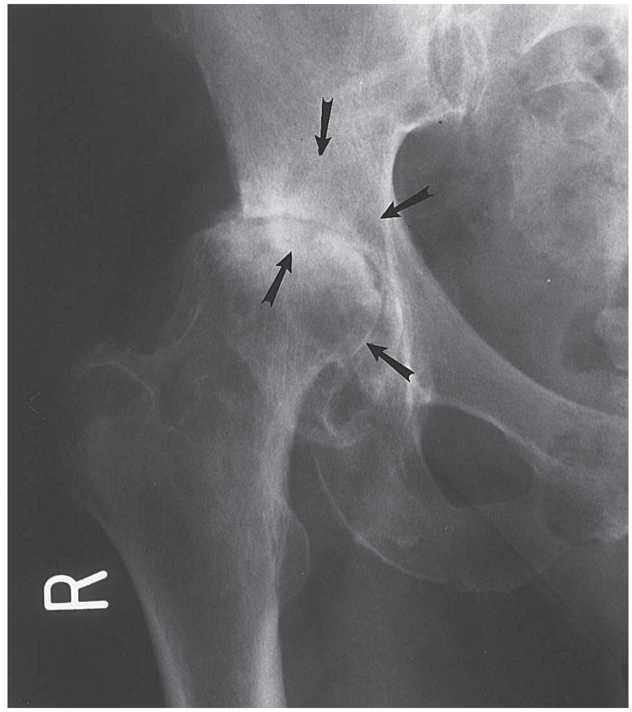

FIGURE 11.6 Severe osteoarthritis of the hip with pseudocysts. The radiolucent cyst-like areas (*arrows*) are caused by intrusion of synovial fluid into areas of subchondral bone that have become weakened by microfractures. *(From McKinnis,[62] p 62, with permission.)*

Principles of Management: Osteoarthritis

Pain, joint stiffness, decreased muscle performance, and decreased aerobic capacity affect the quality of life and increase the risk for disability for the individual with OA.[32] Therapeutic exercise and manual therapy interventions are important in the comprehensive management of OA. Management guidelines are summarized in Box 11.4.

- *Patient instruction*. Education includes teaching the patient about the disease of OA, how to protect the joints while remaining active, and how to manage the symptoms. Instruct the patient in a home program of safe exercises to improve muscle performance, ROM, and endurance.
- *Pain management—Early stages.* Pain and feelings of "stiffness" are common complaints during the early stages. Pain usually occurs because of excessive activity and stress on the involved joint and is relieved with rest. Brief periods of stiffness occur in the morning or after periods of inactivity. This is due to gelling of the involved joints after periods of inactivity.[2] Movement relieves the stasis and feelings of stiffness. Help the patient find a balance between activity and rest and correct biomechanical stresses in order to prevent, retard, or correct the mechanical limitations.
- *Pain management—Late stages.* During the late stages of the disease, pain is often present at rest. The pain is probably from secondary involvement of subchondral bone, synovium, and the joint capsule. In the spine, if boney growth encroaches on the nerve root, there may be radicular pain

BOX 11.4 MANAGEMENT GUIDELINES—
Osteoarthritis

Structural/Functional Impairments, Activity Limitations, and Participation Restrictions:

Pain with mechanical stress or excessive activity
Pain at rest in the advanced stages
Stiffness after inactivity
Limitation of motion
Muscle weakness
Decreased proprioception and balance
Functional limitations in ADLs and IADLs

Plan of Care	Intervention
1. Educate the patient.	1. Teach about deforming forces and prevention. Teach home exercise program to reinforce interventions and minimize symptoms.
2. Decrease effects of stiffness.	2. Active ROM Joint-play mobilization techniques
3. Decrease pain from mechanical stress and prevent deforming forces.	3. Splinting and/or assistive equipment to minimize stress or to correct faulty biomechanics, strengthen supporting muscles. Alternate activity with periods of rest.
4. Increase ROM.	4. Stretch muscle, joint, or soft tissue restrictions with specific techniques.
5. Improve neuromuscular control, strength, and muscle endurance.	5. Low-intensity resistance exercises and muscle repetitions.
6. Improve balance.	6. Balance training activities.
7. Improve physical conditioning.	7. Nonimpact or low-impact aerobic exercise.

PRECAUTIONS: When strengthening supporting muscles, increased pain in the joint during or following resistive exercises probably means that too great a weight is being used or stress is being placed at an inappropriate part of the ROM. Analyze the joint mechanics and at what point during the range the greatest compressive forces are occurring. Maximum resistance exercise should not be performed through that ROM.

(see chapter 15). Emphasize activity modification and use of assistive devices and/or splints to minimize joint stress. Pain that cannot be managed with activity modification (as described in the following bullet) and analgesics is usually an indication for surgical intervention.

- *Assistive and supportive devices and activity.* With progression of the disease, the boney remodeling, swelling, and contractures alter the transmission of forces through the joint, which further perpetuates the deforming forces and creates joint deformity. Functional activities become more difficult. Adaptive or assistive devices, such as a raised toilet seat, cane, or walker, may be needed to decrease painful stresses and maintain function. Shock-absorbing footwear may decrease the stresses in OA of the knees.[31] Aquatic therapy and group-based exercise in water decreases pain and improves physical function in patients with lower extremity OA.[25]
- *Resistance exercise.* Progressive weakening in the muscle occurs either from inactivity or from inhibition of the neuronal pools. Weak muscles may add to the joint dysfunction.[2] Strong muscles protect the joint. Use resistance exercises, within the tolerance of the joint, as part of the patient's exercise program. Avoid deforming forces and heavy weights that the patient cannot control or that cause joint pain. Adaptations include the use of multiple-angle isometrics in pain-free positions, applying resistance only through arcs of motion that are not painful, and use of a pool to decrease weight-bearing stresses and improve functional performance.[37]
- *Stretching and joint mobilization.* Use stretching and joint mobilization techniques to increase mobility. Teach the patient self-stretching/flexibility exercises and the importance of movement to counteract the developing restrictions.

FOCUS ON EVIDENCE

In a single-blind, randomized clinical trial of 109 patients with OA of the hip, specific manipulations and mobilizations of the hip joint were reported to have a greater success rate than active exercise for improving muscle function and joint motion. Outcomes measured were perceived improvement after treatment (81% vs. 50%), pain, stiffness, hip function, and ROM.[45]

- *Balance activities.* Joint position sense may be impaired.[96] See Chapter 8 for principles and description of balance exercises. Nontraditional forms of exercise, such as Tai Chi, have been found to be effective for improving balance in patients with OA.[89]
- *Aerobic conditioning.* Instruct the patient in exercises designed to improve cardiopulmonary function.[13] The choice of exercise should have low impact on the joints, such as walking, biking, or swimming. Avoid activities that cause repetitive intensive loading of the joints, such as jogging and jumping.

FOCUS ON EVIDENCE

Recently published clinical practice guidelines based on a systematic review of randomized controlled and observational studies highlight the importance of therapeutic exercise and physical activity to increase strength, manage pain, and improve aerobic capacity and functional status in patients with OA.[15]

Two systematic reviews of studies designed to examine evidence of the effects of exercise in the management of hip and knee OA describe support for aerobic exercise and strengthening exercises to reduce pain and disability.[75,76] The consensus of expert opinion cited by Roddy[75] is that there are few contraindications and that exercise is relatively safe in patients with OA, but that exercise should be individualized and patient-centered with consideration for age, comorbidity, and general mobility.

In another study that followed 285 patients with knee OA for 3 years, investigators found that factors that protected the individuals from poor functional outcomes included strength and activity level, as well as factors such as mental health, self-efficacy, and social support.[82]

Fibromyalgia and Myofascial Pain Syndrome

Fibromyalgia (FM) and myofascial pain syndrome (MPS) are chronic pain syndromes that are often confused and interchanged. Each has a distinct proposed etiology. Individuals with FM process nociceptive signals differently from individuals without FM,[78,90] and individuals with MPS have localized changes in the muscle.[39,81,85,90] Although there are some similarities, the differences are significant and determine the method of treatment. They are summarized in Table 11.2.

TABLE 11.2 Similarities and Differences Between Fibromyalgia and Myofascial Pain Syndrome

Similarities	
Pain in muscles Decreased ROM Postural stresses	
Differences	
Fibromyalgia	***Myofascial Pain Syndrome***
Tender points at specific cites	Trigger points in muscle
No referred patterns of pain	Referred patterns of pain
No tight band of muscle	Tight band of muscle
Fatigue and waking unrefreshed	No related fatigue complaints

Fibromyalgia

Fibromyalgia, as defined by the American College of Rheumatology in 1990,[1a,98] is a chronic condition characterized by widespread pain that covers half the body (right or left half, upper or lower half) plus the axial skeleton, and has lasted for more than 3 months. Additional symptoms include 11 of 18 tender points at specific sites throughout the body (Fig. 11.7),

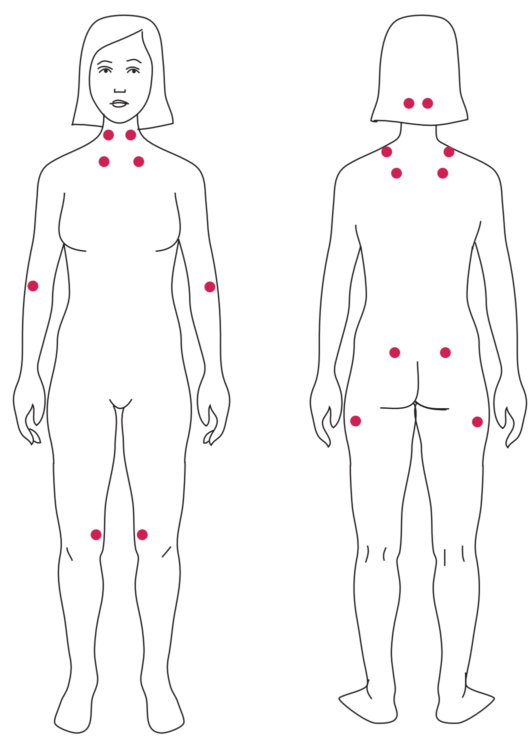

FIGURE 11.7 Fibromyalgia tender points.

nonrestorative sleep, and morning stiffness. A final common problem is fatigue with subsequent diminished exercise tolerance.[98]

FOCUS ON EVIDENCE

In 2010, Wolfe and associates[97] developed preliminary diagnostic criteria to complement the ACR-specific criteria, including the measurement of symptom severity. The authors recommend the following: widespread pain index (WPI) ≥7 *and* symptom severity (SS) scale ≥5, *OR* WPI 3 to 6 *and* SS ≥9. These criteria correctly classified 88.1% of individuals with FM determined from the ACR classification without tender point palpation. The SS scale includes items such as somatic symptoms, not feeling refreshed after sleeping, fatigue, and cognition.

Prevalence of FM

It is estimated that 2% of the population—nearly 5 million adults 18 years old or older—have FM, with women affected far more than men (3.4% to 0.5%). In addition, the prevalence increases with age, with 7.4% of women ages 70 to 79 affected.[52]

Characteristics of FM

The characteristics of FM include the following.[1a,90]

- The first symptoms of FM can occur at any age but usually appear during early to middle adulthood.
- For many of those diagnosed, the symptoms develop after physical trauma such as a motor vehicle accident or a viral infection.
- Although the symptoms vary from individual to individual, there are several hallmark complaints. Pain is usually described as muscular in origin and is predominantly reported in the scapula, head, neck, chest, and low back.
- Another common report is a significant fluctuation in symptoms. Some days an individual may be pain-free, whereas other days the pain is markedly increased. Most individuals report that, when they are in a cycle in which the symptoms are diminished, they try to do as much as possible. This is usually followed by several days of worsening symptoms and an inability to carry out their normal daily activities. This is often the response to exercise.
- Individuals with FM have a higher incidence of tendonitis, headaches, irritable bowel, temporal mandibular joint dysfunction, restless leg syndrome, mitral valve prolapse, anxiety, depression, and memory problems.

Factors Contributing to a Flare

Although FM is a noninflammatory, nondegenerative, nonprogressive disorder, several factors may affect the severity of symptoms. These factors include environmental stresses, physical stresses, and emotional stresses. FM is not caused by these various stresses, but it is aggravated by them.

- Environmental stresses include weather changes, especially significant changes in barometric pressure, cold, dampness, fog, and rain. An additional environmental stress is fluorescent lights.
- Physical stresses include repetitive activities, such as typing, playing piano, vacuuming; prolonged periods of sitting and/or standing; and working rotating shifts.
- Emotional stresses are any normal life stresses.

Management: Fibromyalgia

Research supports the use of exercise,[16,17,19,20,30,57] particularly aerobic exercise, to reduce the most common symptoms associated with FM.

FOCUS ON EVIDENCE

An evidence report from the Cochrane Collaborative[19] summarized the findings of 34 randomized trials related to FM and exercise. The reviewers concluded that aerobic exercise was beneficial in reducing FM symptoms and improving exercise capacity, and resistance exercises might be beneficial in reducing symptoms.

The Ottawa Panel Evidence-Based Clinical Practice Guidelines[16,17] also support the use of aerobic and strengthening exercises.

In addition to exercise, interventions include:

- Prescription medication
- Over-the-counter medication
- Instruction in pacing activities, in an attempt to avoid fluctuations in symptoms
- Coginitive Behavior therapy
- Avoidance of stress factors
- Decreasing alcohol and caffeine consumption
- Diet modification.

CLINICAL TIP

When beginning any type of exercise with individuals with FM,[16,17,19,46] it is best to begin at lower levels than recommended by the American College of Sports Medicine[4] for aerobic and strengthening and to slowly increase the activity. If the exercise leads to an increase in FM symptoms, reduce the intensity, while encouraging continued participation in the exercise.

Myofascial Pain Syndrome

Myofascial pain syndrome (MPS) is defined as a chronic, regional pain syndrome.[85] The hallmark classification of MPS comprises the myofascial trigger points (MTrPs) in a

muscle that have a specific referred pattern of pain (Fig. 11.8), along with sensory, motor, and autonomic symptoms.[29,86,87]

The *trigger point* is defined as a hyperirritable area in a tight band of muscle. The pain from these points is described as dull, aching, and deep. Additional impairments from the trigger points include decreased ROM when the muscle is being stretched, decreased strength in the muscle, and increased pain with muscle stretching. The trigger points may be active (producing a classic pain pattern) or latent (asymptomatic unless palpated).

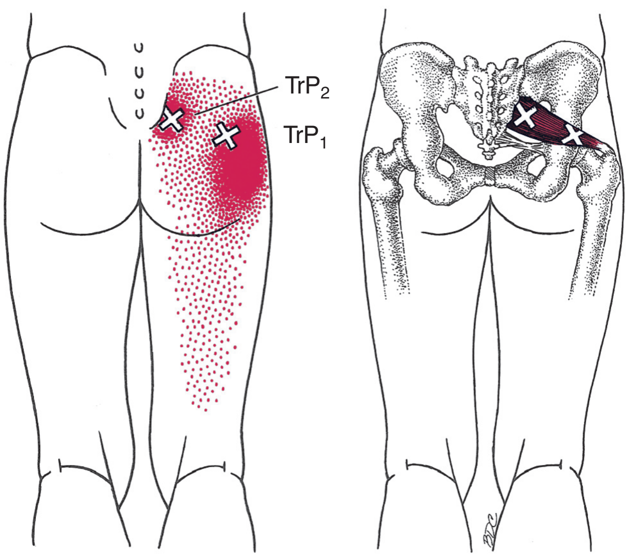

FIGURE 11.8 Composite pattern of pain (dark red) referred from trigger points (TrPs) (Xs) in the right piriformis muscle (medium red). The lateral X (TrP_1) indicates the most common TrP location. The red stippling locates the spillover part of the pattern that may be felt as less intense pain than that of the essential pattern (solid red). The spillover pain may be absent. *(From Travell, JG, Simmons, DG: Myofascial Pain and Dysfunction: The Trigger Point Manual: The Lower Extremities, Vol 2.* Baltimore: Williams & Wilkins, 1992, p 188, with permission.*)*

Possible Causes of Trigger Points

Although the etiology of trigger points is not completely understood, some potential causes are:[85-87]

- Chronic overload of the muscle that occurs with repetitive activities or that maintain the muscle in a shortened position.
- Acute overload of muscle, such as slipping and catching oneself, picking up an object that has an unexpected weight, or following trauma such as in a motor vehicle accident.
- Poorly conditioned muscles compared to muscles that are exercised on a regular basis.
- Postural stresses such as sitting for prolonged periods of time, especially if the workstation is not ergonomically correct, and leg length differences.
- Poor body mechanics with lifting and other activities.

FOCUS ON EVIDENCE

Recently researchers have looked at the contribution of myofascial trigger points as a contributing factor in chronic headaches,[80] tension type headaches,[34,35] mechanical neck pain,[33] and shoulder disorders.[43,55,80] Lucas and associates[54] investigated the muscle activation pattern (MAP) of scapular muscles during arm elevation in pain-free individuals without trigger points and pain-free individuals with latent trigger points (LTrP). The LTrP group had a significant difference in MAP ($p<0.05$). These individuals were then treated with either a placebo or active intervention to deactivate the trigger point, and the MAP was reassessed. There was a significant difference ($p<0.05$) in MAP after deactivation of the LTrP.

Management: Myofascial Pain Syndrome

Treatment consists of three main components:[1,56,85-87,93]

- Correct contributing factors to chronic overload of the muscle.
- Eliminate the trigger point. Several techniques are used to eliminate trigger points:
  - Contract-relax-passive stretch done repeatedly until the muscle lengthens
  - Contract-relax-active stretch also done in repetition
  - Trigger point release
  - Spray and stretch
  - Modalities
  - Dry needling or injection
- Strengthen the muscle.

CLINICAL TIP

If the cause of the trigger point in myofascial pain syndrome is a chronic overload of the muscle, eliminate the contributing factor prior to addressing the trigger point. Initiate muscle strengthening when ROM is restored and the trigger point has been addressed.

Osteoporosis

Osteoporosis is a disease of bone that leads to decreased mineral content and weakening of the bone. This weakening may lead to fractures, especially of the spine, hip, and wrist. Approximately 10 million Americans have osteoporosis, 80% of them women, and an additional 34 million individuals are at increased risk due to decreased bone mass.[68] The diagnosis of osteoporosis is determined by the T-score of a bone mineral density (BMD) scan. The *T- score* is the number of standard deviations above or below a reference value (young, healthy Caucasian women). The World

Health Organization (WHO) has established the following criteria.[67,94]

- Normal: –1.0 or higher
- Osteopenia: –1.0 to –2.4
- Osteoporosis: –2.5 or less

A decrease of 1 standard deviation represents a 10% to 12% loss of BMD.

Risk Factors

Primary osteoporosis. Risk factors for developing primary osteoporosis include being postmenopausal, Caucasian or Asian descent, family history, low body weight, little or no physical activity, diet low in calcium and vitamin D, and smoking.[68] Additional risk factors include prolonged bed rest and advanced age.

Secondary osteoporosis. Secondary osteoporosis develops owing to other medical conditions (i.e., gastrointestinal diseases, hyperthyroidism, chronic renal failure, excessive alcohol consumption) and the use of certain medications such as glucocorticoids.[67,94] Regardless of etiology, osteoporosis is detected radiographically by cortical thinning, osteopenia (increased bone radiolucency), trabecular changes, and fractures (Figs. 11.9 and 11.10).[62]

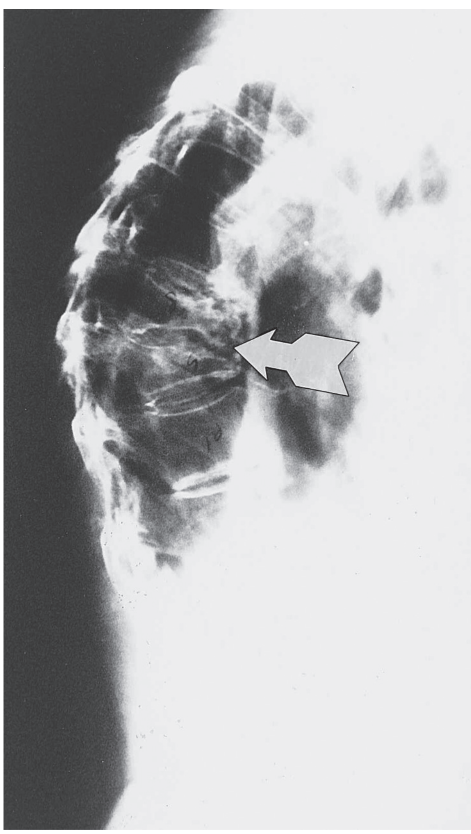

FIGURE 11.9 Osteoporosis of the spine with multiple compression fractures. The arrow points to the T8-T9 disc space, which is deformed by the collapse of these two vertebrae from multiple compression fractures. This 94-year-old woman has severe kyphosis of the thoracic spine (also known as a gibbous deformity) accentuated by vertebral collapse at multiple levels. *(From McKinnis,[62] p 64, with permission.)*

FIGURE 11.10 Osteoporosis is evident in this knee by the accentuation of the remaining trabeculae. The trabeculae have diminished in number and thickness, and the remaining vertically oriented trabeculae stand out as thin, delicate line images. *(From McKinnis,[62] p 64, with permission.)*

Prevention of Osteoporosis

The National Osteoporosis Foundation (NOF) recommends five ways to prevent osteoporosis.[69]

- Diet rich in calcium and vitamin D
- Weight-bearing exercise
- Healthy lifestyle with moderate alcohol consumption and no smoking
- Talking to a health care provider
- Testing bone for its density and medication if needed

Bone is living tissue, continually replacing itself in response to the daily demands placed on it. Normally, this continual replacement keeps our bone at its optimum strength. Cells in bone called osteoclasts resorb bone, especially if calcium is needed for particular body functions and not enough is obtained in the diet. Another type of cell, the osteoblast, builds bone. This cycle is usually kept in balance with bone resorption equaling bone replacement until the third decade of life. At this point, peak bone mass should be reached. With increasing age, there is a shift to greater resorption. For women, resorption is accelerated during menopause owing to the decrease in estrogen.[67,70,94]

Physical Activity

Physical activity has been shown to have a positive effect on bone remodeling. In children and adolescents, this activity may increase the peak bone mass. In adults, it has been shown to maintain or increase bone density; in the elderly, it has been shown to reduce the effects of age-related or disuse-related bone loss.[67] Maintenance of, or an increase in, bone density is important for preventing fractures associated with osteoporosis. Weak bones due to osteoporosis have been attributed to causing more than 1.5 million fractures per year at a cost of $19 billion dollars. Many of these individuals never return to their previous functional level.[68,94]

Effects of Exercise

Muscle contraction (e.g., strengthening exercises, resistance training) and mechanical loading (weight bearing) deform bone. This deformation stimulates osteoblastic activity and improves BMD.[88]

FOCUS ON EVIDENCE

Martyn-St James and Carroll[59] completed a meta-analysis of prescribed walking programs on BMD at the hip and spine in postmenopausal women. Results reported no increase in BMD at the spine, but a significant increase at the femoral neck.

Huntoon, Schmidt, and Sinaki[47] completed a retrospective analysis of medical records comparing the refracture rate following vertebral compression fractures (VCF) in patients instructed in a back extension program following percutaneous vertebroplasty (PVP) to those who did not perform the exercises. The nonexercise group refractured within an average of 4.5 months, whereas the exercise group average time to refracture was 20.4 months.

An evidence report from the Cochrane Collaborative[11] summarized the findings of 18 randomized trials related to exercise and osteoporosis in women. The reviewers concluded that exercise, particularly fast walking, was effective on the BMD of the spine and hip. Resistance and weight-bearing exercise were also beneficial on the BMD of the spine.

Recommendations for Exercise

The NOF recommends weight-bearing exercise in the prevention of osteoporosis but does not specify what type of exercise or how often it should be done. Based on current research, the following recommendations are made.*

- Weight-bearing exercise, such as walking, jogging, climbing stairs, jumping
- Nonweight-bearing exercise, such as with a bicycle ergometer
- Resistance (strength) training of 8 to 10 exercises that target major muscle groups

*7,9,11,21,22,36,38,40,41,47,48,50,51,59,66,67,69,71,72,77,83,94

Mode: Aerobic

Frequency. Five or more days per week.

Intensity. Thirty minutes of moderate intensity (fast walking) or 20 minutes of vigorous intensity (running). Doing three short bouts per day of 10 minutes of activity is acceptable.

Mode: Resistance

Frequency. Two to three days per week with a day of rest in between each bout of exercise.

Intensity. Eight to 12 repetitions that lead to muscle fatigue.

CLINICAL TIP

The Borg rate of perceived exertion scale (RPE) is a good indicator of how difficult an exercise is for an individual.[12] A score of 16/20 is based on a 15-grade RPE scale (6 to 20). The individual rates how hard he or she is working (7 = very, very light; 13 = somewhat hard; 19 = very, very hard).

Precautions and Contraindications

- Because osteoporosis changes the shape of the vertebral bodies (they become more wedge-shaped), leading to kyphosis, flexion activities and exercise, such as supine curl-ups and sit-ups, as well as the use of sitting abdominal machines should be avoided. Stress into spinal flexion increases the risk of a vertebral compression fracture.
- Avoid combining flexion and rotation of the trunk to reduce stress on the vertebrae and the intervertebral discs.
- When performing resistance exercise, it is important to increase the intensity progressively but within the structural capacity of the bone.

NOTE: Refer to Chapter 6 for a discussion of pathological fractures and precautions that should be taken during resistance exercise, identified in Box 6.12.

CLINICAL TIP

Utilizing a multimodal program of weight-bearing exercise, balance activities, and strengthening may help reduce the risk of falls and subsequent hip fractures in individuals with osteoporosis.[28,65]

Fractures and Posttraumatic Immobilization

A fracture is a structural break in the continuity of a bone, an epiphyseal plate, or a cartilaginous joint surface.[79] When there is a fracture, some degree of injury also occurs to the soft

tissues surrounding the bone. Depending on the site of the fracture, the related soft tissue injury could be serious if a major artery or peripheral nerve is also involved. If the fracture is more central, the brain, spinal cord, or viscera could be involved. Causes and types of fractures are summarized in Table 11.3 and are illustrated in Figures 11.11, 11.12, and 11.13.

A fracture is identified by[79]:

- *Site:* diaphyseal, metaphyseal, epiphyseal, intra-articular
- *Extent:* complete, incomplete
- *Configuration:* transverse, oblique or spiral, comminuted (two or more fragments)
- *Relationship of the fragments:* undisplaced, displaced
- *Relationship to the environment:* closed (skin in tact), open (fracture or object penetrated the skin)
- *Complications:* local or systemic; related to the injury or to the treatment

The diagnosis, reduction, alignment, and immobilization for healing of a fracture are medical procedures and are not discussed in this text. There are times, though, when the therapist provides the initial screening following a traumatic event or examines a patient following repetitive microtrauma; moreover, a patient may sustain an injury while at a therapy session. Hence, the therapist must be aware of symptoms and signs of a potential fracture. If a fracture is suspected, refer the patient for radiographic examination, medical diagnosis, and management. Box 11.5 summarizes the typical symptoms and signs of a possible fracture.

TABLE 11.3 Causes and Types of Fractures[79]

Force	Effect on Bone	Type of Fracture
Bending (angulatory)	Long bone bends causing failure on convex side of bend	Transverse or oblique fracture Greenstick fracture in children
Twisting (torsional)	Spiral tension failure in long bone	Spiral fracture
Straight pulling (traction)	Tension failure from pull of ligament or muscle	Avulsion fracture
Crushing (compression)	Usually in cancellous bone	Compression fracture Torus (buckle) fracture in children
Repetitive microtrauma	Small crack in bone unaccustomed to the repetitive/rhythmic stress	Fatigue fracture or stress fracture
Normal force on abnormal bone	Such as with osteoporosis, boney tumor, or other diseased bone	Pathological fracture

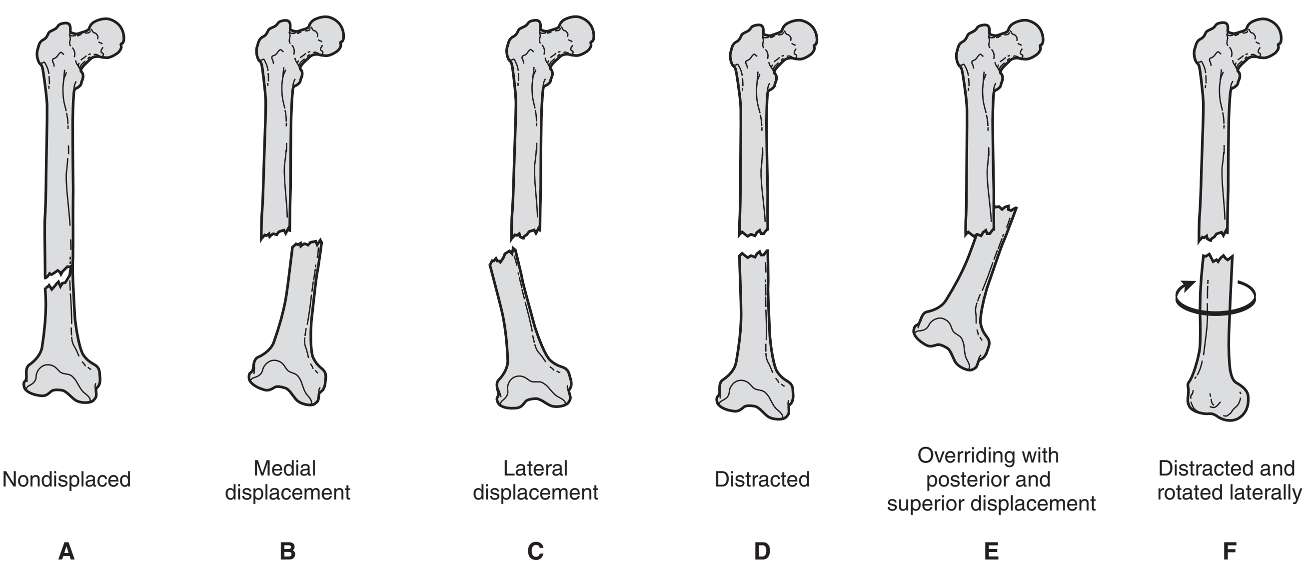

FIGURE 11.11 (A–F) The *position* of fracture fragments may be described by how the *distal* fragment displaces in relationship to the *proximal* fragment. *(From McKinnis,[62] p 84, with permission.)*

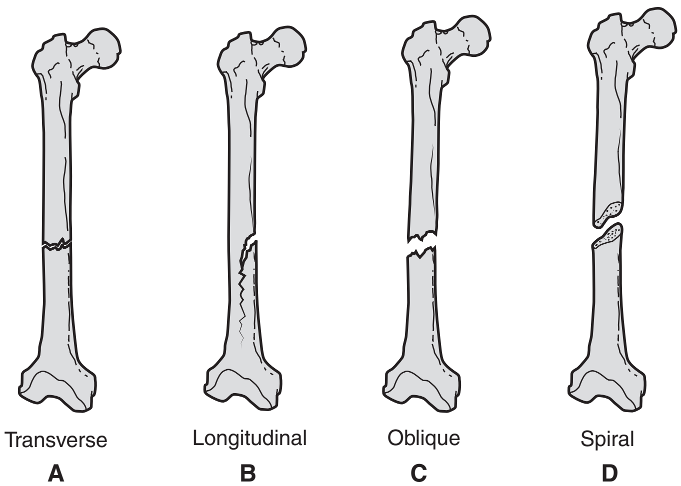

FIGURE 11.12 (A–D) Directions of fracture lines are described in reference to the longitudinal axis of the bone. *(From McKinnis,[62] p 85, with permission.)*

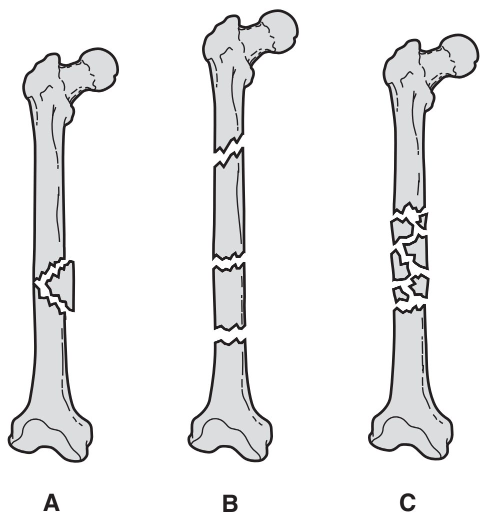

FIGURE 11.13 *Comminuted* fractures are fractures with more than two fragments. Some frequently occurring comminuted fracture patterns are **(A)** the wedge-shaped or butterfly pattern and **(B)** a two- or three-segmented level fracture. **(C)** Other fractures with multiple fragments, be it several or several hundred, are still described as comminuted. *(From McKinnis,[62] p 85, with permission.)*

BOX 11.5 Symptoms and Signs of a Possible Fracture

The following should alert the therapist to a possible fracture.

- History of a fall, direct blow, twisting injury, accident
- Localized pain aggravated by movement
- Muscle guarding with passive movement
- Decreased function of the part
- Swelling, deformity, abnormal movement (may or may not be obvious)
- Sharp, localized tenderness at the site

Risk Factors

Risk factors for fracture include[10]:

- Sudden impact (e.g., accidents, abuse, assult)
- Osteoporosis (women > men)
- History of falls (expecially with increased age, low body mass index, and low levels of physical activity

Bone Healing Following a Fracture

Fracture healing has (1) an inflammatory phase in which there is hematoma formation and cellular proliferation; (2) a reparative phase in which there is callous formation uniting the breach and ossification; and (3) a remodeling phase in which there is consolidation and remodeling of the bone.[10,79]

Cortical Bone Healing

Inflammatory Phase

When the dense cortical bone of the shaft of a long bone is fractured, the tiny blood vessels are torn at the site, resulting in internal bleeding followed by normal clotting. The amount of bleeding depends on the degree of fracture displacement and amount of soft tissue injury in the region.

Reparative Phase

The early stages of healing take place in the hematoma. Osteogenic cells proliferate from the periosteum and endosteum to form a thick callus, which envelopes the fracture site. At this stage, the callus does not contain bone and is, therefore, radiolucent.

As the callus starts to mature, the osteogenic cells differentiate into osteoblasts and chondroblasts. Initially, the chondroblasts form cartilage near the fracture site, and the osteoblasts form primary woven bone.

Remodeling Phase

- *Stage of clinical union.* When the fracture site is firm enough that it no longer moves, it is clinically united. This occurs when the temporary callus consisting of the primary woven bone and cartilage surrounds the fracture site. The callus gradually hardens as the cartilage ossifies (endochondral ossification). On radiographic examination, the fracture line is still apparent, but there is evidence of bone in the callus. Usually at this stage, immobilization is no longer required. Movement of the related joints is allowed with the caution of avoiding deforming forces at the site of the healing fracture. When assessing the site, no movement of the fracture site or pain should be felt by the patient or therapist.
- *Stage of radiological union.* The bone is considered radiographically healed, or consolidated, when the temporary callus has been replaced by mature lamellar bone. The callus is resorbed, and the bone returns to normal.

Rigid Internal Fixation

Sometimes it is necessary to surgically apply an internal fixation device, such as a rod or a plate with screws, to protect a

healing bone. This allows the bone to be kept stable as it heals, but disuse osteoporosis of the bone under the device occurs because normal stresses are transmitted through the device and bypass the bone. Usually the fixation device is removed once the fracture is united in order to reverse the osteoporosis. Following removal of the rod or plate, the bone must be protected from excessive stress for several months until the osteoporosis is reversed.

Healing Time

Healing time varies with age of the patient, the location and type of fracture, whether it was displaced, and the blood supply to the fragments. Healing is assessed by the physician using radiological and clinical examinations. Generally, children heal within 4 to 6 weeks, adolescents within 6 to 8 weeks, and adults within 10 to 18 weeks.[10] Several types of abnormal healing may occur. These are summarized in Box 11.6.

Cancellous Bone Healing

When the sponge-like lattice of the trabeculae of cancellous bone fractures (in the metaphysis of long bones and bodies of short bones and flat bones), healing occurs primarily through formation of an internal callus (endosteal) callus. There is a rich blood supply and a large area of boney contact, so union is more rapid than in dense cortical bone.

Cancellous bone is more susceptible to compression forces, resulting in crush or compression fractures. If the surfaces of the fracture are pulled apart, which may occur during reduction of the fracture, healing is delayed.

Epiphyseal Plate Healing

If a fracture involves the epiphyseal plate, there may be growth disturbances and boney deformity as the skeleton continues to mature. The prognosis for growth disturbances depends on the type of injury, age of the child, blood supply to the epiphysis, method of reduction, and whether it is a closed or open injury.

Principles of Management: Period of Immobilization

Local Tissue Response

With immobilization, there is connective tissue weakening, articular cartilage degeneration, muscle atrophy, and contracture development as well as sluggish circulation.[10,26,61] In addition, there is soft tissue injury with bleeding and scar formation.[79] Because immobilization is necessary for bone healing, the soft tissue scar cannot become organized along lines of stress as it develops (described in Chapter 10). Early, nondestructive motion within the tolerance of the fracture site is ideal but usually not feasible unless there is some type of internal fixation to stabilize the fracture site. It is important to keep structures in the related area in a state as near normal as possible by using appropriate exercises without jeopardizing alignment of the fracture site while it is healing. The therapist must be alert to complications that can occur following a fracture (summarized in Box 11.7).

Immobilization in Bed

If bed rest or immobilization in bed is required, as with skeletal traction, secondary physiological changes occur systematically throughout the body. General exercises for the uninvolved portions of the body are initiated to minimize these problems.

Functional Adaptations

If there is a lower extremity fracture, alternative modes of ambulation, such as the use of crutches or a walker, are taught to the patient who is allowed out of bed. The choice of device and gait pattern depends on the fracture site, the type of immobilization, and the functional capabilities of the patient. The patient's physician should be consulted to determine the amount of weight bearing allowed. Management guidelines are summarized in Box 11.8.

Postimmobilization

Impairments

- Decreased ROM, joint play, and muscle flexibility.
- Muscle atrophy with weakness and poor muscle endurance.
- Initially, the patient experiences pain as movement begins, but it should progressively decrease as joint movement, muscle strength, and ROM improve.
- If there was soft tissue damage at the time of the fracture, an inelastic scar restricts tissue mobility in the region of the scar.

BOX 11.6 Types of Abnormal Healing of Fractures

Malunion: The fracture heals in an unsatisfactory position resulting in a boney deformity.
Delayed union: The fracture takes longer than normal to heal.
Nonunion: The fracture fails to unite with a boney union. There may be a *fibrous union* or a *pseudarthrosis*.

BOX 11.7 Complications of Fractures[10]

- *Swelling* that is contained within a compartment (fascial compartment or tight cast) leading to nerve and circulatory compromise.
- *Fat embolism* (may occur with fracture in bones with the most marrow, such as long bones and the pelvis) that migrates to the lungs and blocks pulmonary vessels. This is potentially life-threatening.
- *Problems with fixation devices* such as displacement of screws and breakage of wires
- *Infection* that occurs locally or systemically
- *Refracture*
- *Delayed or malunion*

BOX 11.8 MANAGEMENT GUIDELINES—
Postfracture/Period of Immobilization

Impairments, Activity Limitations, and Participation Restrictions:

Initially, inflammation and swelling

Progressive muscle atrophy, contracture formation, cartilage degeneration, and decreased circulation in the immobilized area

Potential overall body weakening if confined to bed

Limited activity and restricted participation in ADLs, IADLs, and work imposed by the fracture site and method of immobilization used

Plan of Care	Intervention
1. Educate the patient.	1. Teach functional adaptations. Teach safe ambulation, bed mobility.
2. Decrease effects of inflammation during acute period.	2. Ice, elevation
3. Decrease effects of immobilization.	3. Intermittent muscle setting. Active ROM to joints above and below immobilized region.
4. If patient is confined to bed, maintain strength and ROM in major muscle groups.	4. Resistive exercises to major muscle groups not immobilized, especially in preparation for future ambulation

Management: Postimmobilization

Management guidelines are summarized in Box 11.9.

Consultation with the referring physician is necessary to determine if there is clinical or radiological healing. Until the fracture site is radiologically healed, care should be used any time stress is placed across the fracture site, such as when applying resistance or a stretch force or during weight-bearing activities. Once radiologically healed, the bone has normal structural integrity and can withstand normal stress.

The patient is examined to identify impairments and determine the current functional status, activity level, and desired outcome. ROM, joint mobility, and muscle performance as well as any other impairments are measured and documented. Usually all of the joint and periarticular tissues are affected in the region that was immobilized.

Typical interventions include:

- *Joint mobilization.* Joint mobilization techniques are effective for regaining lost joint play without traumatizing the articular cartilage or stressing the fracture site.[49] Intervention begins with gentle stretches and progresses in intensity as joint reaction becomes predictable.
- *PNF Stretching.* Hold-relax and agonist-contraction techniques are used during the postimmobilization period because the intensity can be controlled by the patient. It is important to monitor the intensity of contraction and to not apply the resistive or stretch force beyond the fracture site until there is radiological healing of the bone in order to avoid a bending force across the fracture site. Once the bone is radiologically healed, the stretch force can be applied beyond the fracture site.
- *Functional activities.* The patient can resume normal activities with caution. During the early postimmobilization period, it is important to not traumatize the weakened muscle, cartilage, bone, and connective tissue. Partial weight bearing must be continued for several weeks after a lower extremity fracture until the fracture site is completely healed and able to tolerate full weight bearing.
- *Muscle performance: Strengthening and muscle endurance.* For 2 to 3 weeks following immobilization, because neither the bone nor cartilage can tolerate excessive compressive or bending forces, exercises are initiated with light isometrics. As joint play and ROM improve, progression is made to light resistance through the available range. The resistive force should be applied proximal to the fracture site until the bone is radiologically healed. Once healed, PRE and other more intense dynamic exercises can be initiated.
- *Scar tissue mobilization.* If there is restricting scar tissue, manual techniques to mobilize the scar are used. The choice of technique depends on the tissue involved.

BOX 11.9 MANAGEMENT GUIDELINES— Postfracture/Postimmobilization

Impairments:

Pain with movement, which progressively decreases
Decreased ROM
Decreased joint play
Scar tissue adhesions
Decreased strength and endurance

Plan of Care	Interventions
1. Educate the patient.	1. Inform patient of limitations until fracture site is radiologically healed. Teach home exercises that reinforce interventions.
2. Provide protection until radiologically healed.	2. Use partial weight bearing in lower extremity and nonstressful activities in the upper extremity.
3. Initiate active exercises.	3. Active ROM, gentle multiangle isometrics
4. Increase joint and soft tissue mobility.	4. Initiate joint play stretching techniques (using grades III and IV) with the force applied proximal to the healing fracture site. For muscle stretching, apply the force proximal to the healing fracture site until radiologically healed.
5. Increase strength and muscle endurance.	5. As the ROM increases and the bone heals, initiate resistive and repetitive exercises.
6. Improve cardiorespiratory fitness.	6. Initiate safe aerobic exercises that do not stress the fracture site until it is healed.

PRECAUTIONS: No stretch or resistive forces distal to the fracture site until the bone is radiologically healed. No excessive joint compression or shear for several weeks after the period of immobilization. Use protected weight bearing until the site is radiologically healed.

Independent Learning Activities

Critical Thinking and Discussion

1. Your patient sustained a traumatic knee joint injury in an automobile accident. There is joint effusion, limited ROM, and decreased joint play 2 days after the accident. The patient guards against motion as you approach the end of the available range. Identify the principles of treatment, the goals, and plan of care for this patient. Describe and practice specific therapeutic techniques that you would use for intervention and describe how you would progress the techniques through the stages of healing.
2. Develop a program of interventions for a patient with osteoarthritis in the knees who has pain when ascending and descending steps and has difficulty standing up from a chair. What examination procedures do you want to do? What functional tests do you want to document? How would the program differ for an individual with symptoms of rheumatoid arthritis during a period of active disease (the acute phase)? During a period of remission (the chronic phase)?
3. Describe your plan of care and list specific interventions for a 55-year-old woman who is postmenopausal and has early signs of osteoporosis. What patient instructions would be important to include?
4. An individual sustained a fracture 6 weeks ago, and the limb was just removed from the cast. How does treatment differ from that of other traumatic conditions 6 weeks

postinjury? Describe what precautions you will follow and why they are important.

5. Your patient was involved in a motor vehicle accident 6 months ago. You saw her 3 months ago, but now she has returned with a diagnosis of fibromyalgia (FM). Her physician recommends exercise. Describe your treatment program, taking into consideration the characteristics of FM and the benefits and problems of exercise in this population.

6. Your new patient is a secretary who presents with upper back and neck pain. She describes a gradual onset. She reports sitting at a computer for 6 to 8 hours each day and having to take phone calls on a regular basis as well. You examine the patient and find several active myofascial trigger points. Describe your course of treatment for this patient. How will you address the effect her work has on her problem?

CHAPTER 12

Surgical Interventions and Postoperative Management

An array of injuries, diseases, and disorders of the musculoskeletal system that affect muscles, tendons, ligaments, cartilage, fascia, joint capsules, or bones can cause structural and functional impairment of the upper or lower extremities or the spine, resulting in activity limitations and participation restriction (functional limitation and disability) to such an extent that surgical intervention is required. Ideally, surgery is preceded by a comprehensive examination and evaluation of a patient's impairments and functional status coupled with preoperative patient education and followed by a planned course of postoperative rehabilitation.

This chapter provides an overview of indications for surgical intervention for musculoskeletal pathology, considerations for preoperative management, factors that influence the outcomes of surgery, general guidelines for management during progressive phases of postoperative rehabilitation, and potential complications that can interfere with the achievement of optimal functional outcomes after surgery. The chapter concludes with an overview of the many types of orthopedic surgery procedures that may be undertaken for the management of musculoskeletal conditions of the upper and lower extremities.

Descriptions of selected surgical procedures for common injuries or disorders of each region of the extremities are described in Chapters 17 through 22. In these chapters, guidelines and progressions for postoperative management of specific surgeries are presented that are based on the principles of tissue healing and exercise prescription addressed in Chapter 10, rather than adherence to specific protocols. These principles can be applied by the therapist when designing exercise interventions for patients undergoing current surgical procedures and can also be applied as a basis of rehabilitation in the future as surgical interventions change and evolve.

Indications for Surgical Intervention

Many acute, recurring, or chronic musculoskeletal conditions are managed successfully with conservative (nonoperative) measures, including rest, protection with splinting or use of assistive devices, medication, therapeutic exercise, manual therapy, and functional training, as well as the use of physical agents or electrotherapy. However, if a conservative program has not been successful and one or more impairments continue to significantly compromise a patient's ability to function or if the severity of a patient's condition is such that nonoperative management is not an appropriate option, surgical intervention becomes the treatment of choice. Indications for a variety of musculoskeletal surgeries are identified in Box 12.1.[11,13,15,56]

BOX 12.1 Indications for Surgery for Musculoskeletal Disorders of the Extremities and Spine

- Incapacitating pain at rest or with functional activities
- Marked limitation of active or passive motion
- Gross instability of a joint or boney segments
- Joint deformity or abnormal joint alignment
- Significant structural degeneration
- Chronic joint swelling
- Failed conservative (nonsurgical) or previous surgical management
- Significant loss of function leading to disability as the result of any of the preceding factors

BOX 12.2 Benefits of Preoperative Contact with a Patient

- Examination and evaluation of a patient's preoperative impairments and functional status to establish a baseline for documenting postoperative improvement
- Opportunity to identify and prioritize a patient's needs and understand a patient's goals and functional expectations after surgery
- A basis for establishing rapport for enhanced continuity of care after surgery
- A mechanism for patient education about the scheduled surgery and the components of postoperative rehabilitation

Guidelines for Preoperative and Postoperative Management

Although surgical intervention can correct or reduce adverse effects and impairments (e.g., pain, deformity, instability) associated with musculoskeletal pathology, a carefully planned and progressed rehabilitation program is essential for a patient to achieve optimal functional outcomes after surgery. In an ideal situation, rehabilitation begins with patient education before surgery and continues after surgery with direct intervention from a therapist followed by long-term self-management by the patient.

Considerations for Preoperative Management

Contact with a patient prior to preplanned, elective surgery is advisable whether it occurs on a one-to-one basis between therapist and patient or in a group setting. In the health care environment of the past few decades, authorization for a preoperative visit with an individual patient has become increasingly difficult. However, preoperative contact with a group of patients scheduled for similar surgeries may be possible. The benefits of preoperative contact with a patient are noted in Box 12.2.

There are several possible elements of preoperative management: a comprehensive examination and evaluation of a patient's preoperative status; patient education and an opportunity for the patient to ask questions about the procedure; and postoperative care and sometimes an extended preoperative exercise program.

Preoperative Examination and Evaluation

If a preoperative visit is approved for an individual patient, it enables a therapist to perform a comprehensive, systematic examination to document the patient's impairments and functional status prior to surgery.[55,67] By evaluating the findings of the examination, a therapist can identify the patient's needs, listen to the patient's concerns and anticipated goals, and determine the expected functional outcomes as a result of the surgery.

Testing and measurement of the following areas are of particular importance for determining realistic goals and functionally relevant outcomes of surgery and postoperative rehabilitation.[67] These areas of the examination are also components of the initial and subsequent postoperative evaluations during rehabilitation.

- *Pain.* Quantitatively measure the patient's level of pain with a visual analog scale or a scale that identifies the degree of pain with specific functional activities.
- *Range of motion and joint integrity*. Measure both active and passive range of motion (ROM) of the involved joint or extremity and compare it to the ROM of the uninvolved areas. Check the stability and mobility of joints.
- *Integrity of the skin.* Note the presence of scars from previous injuries or surgeries, particularly those that are adherent and restrict mobility of skin or underlying connective tissue and joints.
- *Muscle performance (strength and endurance)*. Evaluate muscle strength of the affected areas, recognizing that pain adversely affects strength. Assess the functional strength of unaffected body segments in anticipation of postoperative ambulation with assistive devices, transfers, and activities of daily living (ADL).
- *Posture.* Identify the patient's preferred positions for comfort and any postural abnormalities that may affect ROM and function.
- *Gait analysis*. Analyze the gait characteristics, type of supportive or protective devices currently used, and degree of weight bearing tolerated during ambulation. Note any inequality in leg lengths.
- *Functional status.* Identify the patient's preoperative functional activity limitations and functional abilities and his or her perception of disability associated with participation restrictions using a quantitative, self-report measurement tool.

Preoperative Patient Education: Methods and Rationale

Patient education can be initiated preoperatively, either during an individual instruction session with a patient or in a group setting with patients planning to undergo similar surgeries. Some large, acute-care facilities, for example, have reported descriptions of programs for patients scheduled for joint replacement surgery that focus on preoperative group instruction by team members from several disciplines, including nursing, physical therapy, and occupational therapy.[25,41,47] The group program also may include a tour of the operating and recovery rooms. It is believed that programs such as these help a patient understand what to expect the day of surgery and during the early postoperative days and may alleviate some of a patient's anxiety about the surgery and hospital experience.

Preoperative instruction gives a patient an opportunity to become familiar with wound care, any special precautions that must be followed after surgery, and the use of assistive or supportive equipment, such as crutches, a splint, or a sling.[55,67] Of equal importance, it enables a patient to practice and learn early postoperative exercises without being hampered by postoperative pain or the side effects of pain medication, such as disorientation and drowsiness.[55,67] If surgery is scheduled on an outpatient basis, which is a growing trend, preoperative instruction enables a patient to be safe at home during the early postoperative days and to begin postoperative exercises at home the day of or after surgery before follow-up by a therapist at a later time.

Components of Preoperative Patient Education

- *Overview of the plan of care*. Explain the overall plan of care the patient can expect during the postoperative period.
- *Postoperative precautions.* Advise the patient of any precautions or contraindications to positioning, movement, or weight bearing that must be followed postoperatively.
- *Bed mobility and transfers.* Teach the patient how to move in bed or perform wheelchair transfers safely, incorporating necessary postoperative precautions.
- *Initial postoperative exercises.* Teach the patient any exercises that will be started during the very early postoperative period. These exercises often include:
  - *Deep-breathing and coughing exercises.* Explain the rationale for performing deep-breathing exercises periodically throughout the day.
  - *Active ankle exercises (pumping exercises).* Teach the patient how to reduce postoperative venous stasis and decrease the risk of deep vein thrombosis (DVT).
  - Gentle muscle-setting exercises of immobilized joints.
- *Gait training.* Teach the use of any supportive devices, such as crutches or a walker, that may be needed for protected weight bearing during ambulation after surgery.
- *Wound care.* Explain or reinforce postoperative care of the incision for optimal wound healing.

An Extended Preoperative Exercise Program

The rationale for implementing an exercise program well before a planned surgical procedure is to reduce impairments, such as long-standing strength and ROM deficits, that have developed as the result of a chronic musculoskeletal condition in order to achieve optimal postoperative functional outcomes.[42,68]

A preoperative exercise program may be particularly beneficial if a prolonged period of immobilization or reduced weight bearing is necessary after surgery.

FOCUS ON EVIDENCE

A number of studies have been conducted to determine the effectiveness of an exercise program initiated prior to a planned orthopedic surgical procedure. Results of such studies have been mixed. Kean and colleagues[42] studied the functional impact of a strengthening program initiated prior to high tibial osteotomy in a relatively young, active group of patients with medial compartment osteoarthritis (OA). Fourteen individuals (13 men and 1 woman, mean age 48 years) participated in a supervised isokinetic resistance training program for the quadriceps and hamstrings muscle groups 3 times a week for 12 weeks prior to surgery, leading to significant gains in strength. They also participated in postoperative rehabilitation. Six months following surgery, the functional status of the experimental group was compared with a matched control group of patients who also had undergone high tibial osteotomy and postoperative rehabilitation, but had not participated in preoperative resistance training. At 6 months postoperatively, the preoperative resistance training group scored significantly better than the control group on two subscales (ADL and recreational/sports participation) of a quantitative measurement tool designed to assess function in individuals with knee arthritis. These results suggest that preoperative strength gains may be beneficial to postoperative functional outcomes following high tibial osteotomy.

In contrast, Rooks and associates,[68] who studied a group of patients who were scheduled to undergo total hip or knee arthroplasty, found that despite a 20% increase in lower extremity strength as the result of a preoperative exercise program, there were no significant improvements in postoperative functioning compared with that of a control group. It should be noted, however, that the resistance training programs in these two studies were different, and the patients in the pre- and postarthroplasty study were substantially older and tended to have more advanced arthritis than the patients who underwent high tibial osteotomy.

Considerations for Postoperative Management

A well-planned rehabilitation program, composed of a carefully progressed sequence of therapeutic exercise interventions, functional training, and ongoing patient education, is

fundamental to the patient's postoperative care. Appropriate rehabilitative management takes many factors into consideration, any of which may affect the components and progression of a patient's postoperative program. These factors are noted in Box 12.3. Each of the factors also influences the postoperative functional outcomes for a patient and the ultimate success of the surgical procedure.

To design a safe, effective, efficient rehabilitation program for a patient, a therapist, as a member of the rehabilitation team, must understand the indications and rationale for a particular surgical procedure, become familiar with the procedure itself, be aware of special precautions related to the surgery, and communicate effectively with the patient, surgeon, and other members of the rehabilitation team.[34]

BOX 12.4 Inspection of the Surgical Incision

- Check for signs of redness or tissue necrosis along the incision(s) and around sutures.
- Palpate along the incision and note signs of tenderness and edema.
- Palpate to determine evidence of increased heat.
- Check for signs of drainage; note color and amount of drainage on the dressing.
- Note the integrity of an incision across a joint *during and after* exercise.
- As the incision heals, check the mobility of the scar.

Postoperative Examination and Evaluation

Every individually designed postoperative rehabilitation program must be based on initial and ongoing examinations of a patient. In addition to the components of a preoperative examination noted previously in this section, an assessment of integumentary integrity is important after surgery. The incision should be inspected before and after each exercise session to identify any evidence of wound infection or delayed healing. Inspection of the surgical site includes the items noted in Box 12.4.

Phases of Postoperative Rehabilitation

Postoperative rehabilitation typically is divided into phases, containing goals and suggested interventions for each phase. Phases are identified in several ways: by the overlapping phases of tissue healing (acute/inflammatory, subacute/proliferative, chronic remodeling); by the level of difficulty of activities (initial, intermediate, advanced); by the degree of protection of healing tissues (maximum, moderate, minimum protection); or simply by sequential numbering (e.g., I, II, III).

BOX 12.3 Factors That Influence the Components, Progression, and Outcomes of a Postoperative Rehabilitation Program

- Extent of tissue pathology or damage
  - Size or severity of the lesion
- Type and unique characteristics of the surgical procedure
- Patient-related factors
  - Age, extent of preoperative impairments, and functional limitations
  - Health history, particularly use of medications and diabetes
  - Lifestyle history, including use of tobacco
  - Needs, goals, expectations, and social support
  - Level of motivation and ability to adhere to an exercise program
- Stage of healing of involved tissues
- Characteristics of types of tissues involved
  - Response to immobilization and remobilization
- Integrity of structures adjacent to involved tissues
- Philosophy of the surgeon

As with nonoperative management of musculoskeletal pathology, these phases reflect the stages of healing of involved soft tissue and bone. In addition, phases of postoperative rehabilitation must take into account the characteristics of the surgical procedure, such as the type of surgical approach or tissue fixation.

During each phase of postoperative rehabilitation, the goals and the plan of care, including therapeutic exercise interventions, change. For example, early after surgery, the emphasis of management focuses on minimizing pain, preventing postoperative complications, and resuming a safe level of functional mobility while protecting the surgical site. Later, as tissues heal and the patient recovers from surgery, interventions are directed toward restoring or improving ROM, strength, neuromuscular control, stability, balance, and muscular and cardiopulmonary endurance as well as the patient's ability to perform all necessary and desired functional activities.

Phases of postoperative rehabilitation do not take into account the individual qualities, needs, and abilities of each patient. Therefore, they are not prescriptive but rather are intended as general guidelines for management. To develop an individualized rehabilitation program for a patient, suggested guidelines for each phase should be modified based on the results of ongoing postoperative examination of the patient.

Without disregarding the differences among various surgical procedures and the fact that each patient's recovery after surgery is unique, guidelines for postoperative rehabilitation in this section are divided into three broad, overlapping phases based on the degree of protection of operated structures. The characteristics of these three phases are as follows.

- ***Maximum protection phase.*** This is the initial postoperative period when protection of operated tissues is paramount in the presence of tissue inflammation and pain. After some surgeries, immobilization of the operated area is necessary during this phase. After other surgeries, it is advisable to place low-level stresses on operated tissues soon after surgery, making early passive or assisted ROM

within a protected range or within a patient's tolerance permissible. In both situations, muscle-setting exercises to prevent muscle atrophy also are indicated. The time frame for maximum protection ranges from a few days or a week to a month or 6 weeks depending on the type of surgery and type of tissues involved.

- ***Moderate protection phase.*** This is the intermediate phase of rehabilitation when inflammation has subsided, pain and tenderness are minimal, and tissues are able to withstand gradually increasing levels of stress. Criteria for progression to this phase often include the absence of pain at rest and the availability of at least limited pain-free movement of the operated extremity. Restoring ROM and normal arthrokinematics while tissues continue to heal and remodel, improving neuromuscular control and stability, and gradually increasing strength are emphasized during this phase. Depending on the healing characteristics of the operated tissues, this phase typically begins around 4 to 6 weeks postoperatively and continues for an additional 4 to 6 weeks.
- ***Minimum protection/return to function phase.*** During this advanced phase, little to no protection of operated tissues is required. To progress to this phase, full or almost full, pain-free active ROM should be available, and the joint capsule (if involved) should be clinically stable. Strength necessary to begin this phase varies widely after different procedures. Rehabilitation focuses on restoring functional strength and participating in gradually progressed functional activities. This phase begins anywhere from 6 to 12 weeks postoperatively and may continue until 6 months postoperatively or beyond.

Box 12.5 summarizes management guidelines for postoperative rehabilitation, including common structural and functional impairments that must be addressed and a plan of care with suggested goals and interventions for each phase of rehabilitation.

NOTE: The descriptions of each phase noted in Box 12.5 are general and inclusive of rehabilitation after a variety of surgical interventions. Guidelines that include goals and suggested interventions for each of the phases of postoperative rehabilitation are described for specific surgeries at each region of the spine and extremities in Chapters 15 and17 through 22.

BOX 12.5 MANAGEMENT GUIDELINES—
Postoperative Rehabilitation

Structural and Functional Impairments:

Postoperative pain because of disruption of soft tissue
Postoperative swelling
Potential circulatory and pulmonary complications
Joint stiffness or limitation of motion because of injury to soft tissue and necessary postoperative immobilization
Muscle atrophy because of immobilization
Loss of strength for functional activities
Limitation of weight bearing
Potential loss of strength and mobility of nonoperated joints

Maximum Protection Phase

Plan of Care	Interventions
1. Educate the patient in preparation for self-management.	1. Instruction in safe positioning and limb movements and special postoperative precautions or contraindications.
2. Decrease postoperative pain, muscle guarding, or spasm.	2. Relaxation exercises. Use of modalities such as transcutaneous electrical nerve stimulation (TENS), cold, or heat. Continuous passive motion (CPM) during the early postoperative period.
3. Prevent wound infection.	3. Instruction or review of proper wound care (cleaning and dressing the incision).
4. Minimize postoperative swelling.	4. Elevation of the operated extremity. Active muscle pumping exercises at the distal joints. Use of compression garment. Gentle distal-to-proximal massage.

Continued

BOX 12.5 MANAGEMENT GUIDELINES—
Postoperative Rehabilitation—cont'd

Plan of Care	Interventions
5. Prevent circulatory and pulmonary complications, such as deep vein thrombosis, pulmonary embolus, or pneumonia.	5. Active exercises to distal musculature. Deep-breathing and coughing exercises.
6. Prevent unnecessary, residual joint stiffness or soft tissue contractures.	6. CPM or passive or active-assistive ROM initiated in the immediate postoperative period.
7. Minimize muscle atrophy across immobilized joints.	7. Muscle-setting exercises.
8. Maintain motion and strength in areas above and below the operative site.	8. Active and resistive ROM exercises to nonoperated areas.
9. Maintain functional mobility while protecting the operative site.	9. Adaptive equipment and assistive devices.

Moderate Protection/Controlled Motion Phase

Plan of Care	Interventions
1. Educate the patient.	1. Teach the patient to monitor the effects of the exercise program and make adjustments if swelling or pain increases.
2. Gradually restore soft-tissue and joint mobility.	2. Active-assistive or active ROM within limits of pain. Joint mobilization procedures.
3. Establish a mobile scar.	3. Gentle massage across and around the maturing scar.
4. Strengthen involved muscles and improve joint stability.	4. Multiple-angle isometrics against increasing resistance. Alternating isometrics and rhythmic stabilization procedures. Dynamic exercise against light resistance in open- and closed-chain positions. Light functional activities with operated limb.

Minimum Protection/Return to Function Phase

Plan of Care	Interventions
1. Continue patient education.	1. Emphasize gradual but progressive incorporation of improved muscle performance, mobility, and balance into functional activities.
2. Prevent re-injury or postoperative complications.	2. Reinforce self-monitoring and review the signs and symptoms of excessive use; identify unsafe activities.
3. Restore full joint and soft-tissue mobility, if possible.	3. Joint stretching (mobilization) and self-stretching techniques.
4. Maximize muscle performance, dynamic stability, and neuromuscular control.	4. Progressive strengthening exercises using higher loads and speeds and combined movement patterns. Integrate movements and positions into exercises that simulate functional activities.

BOX 12.5 MANAGEMENT GUIDELINES—
Postoperative Rehabilitation—cont'd

Plan of Care	Interventions
5. Restore balance and coordinated movement.	5. Progressive balance and coordination training.
6. Acquire or relearn specific motor skills.	6. Apply principles of motor learning (appropriate practice and feedback during task-specific training).

PRECAUTIONS: In addition to the precautions already addressed that relate to the stages of tissue repair and healing, there are several additional precautions that are of particular importance to the postoperative patient.

- Avoid positions, movements, or weight bearing that could compromise the integrity of the surgical repair.
- Keep the wound clean to avoid postoperative infection. Monitor for wound drainage and signs of systemic or local infection, such as elevated temperature.
- Avoid vigorous/high-intensity stretching or resistance exercises with soft tissues, such as muscles, tendons, or joint capsules, that have been repaired or reattached for at least 6 weeks to ensure adequate healing and stability.
- Modify level and selection of physical activities, if necessary, to prevent premature wear and tear of repaired or reconstructed soft tissues and joints.

Time-Based and Criterion-Based Progression

Time frames for each phase of rehabilitation vary dramatically from one procedure to another. For example, immediately after an arthroscopic meniscectomy, the maximum protection phase during which movement of the operated joint is limited to passive or assisted motion within a protected range may extend for only 1 day postoperatively. However, after a complex tendon repair in the hand, maximum protection may be required for several weeks.

Although published descriptions of postoperative rehabilitation typically include estimated time frames for each phase of a program, these time periods must be viewed only as general guidelines. Determining a patient's readiness to advance from one phase of postoperative rehabilitation to the next should not be based solely on time but also on the patient's attainment of predetermined criteria, such as the absence of pain or restoration of a particular amount of ROM or level of strength. However, at this time most published guidelines and protocols are time-based and provide little or no information for making criterion-based decisions.

Putting Postoperative Rehabilitation into Perspective

Postoperative rehabilitation after an orthopedic surgical procedure is often a lengthy process. Given the limited number of justifiable therapy sessions available for postoperative management, it is highly unlikely for a therapist to have direct, ongoing contact with a patient through all phases of a rehabilitation program. Consequently, the key to successful postoperative outcomes is effective, long-term self-management that includes therapist-directed, early postoperative patient education followed by a home program of selected interventions—in particular, a progression of exercises that have been carefully taught and are periodically monitored and modified by the therapist during each phase of rehabilitation.[34]

Potential Postoperative Complications and Risk Reduction

There are a number of serious complications that a patient may encounter after surgery, any one of which can adversely affect the outcomes of surgery and postoperative rehabilitation. Complications are sometimes classified as early (within 6 months after surgery) and late. Potential complications are noted in Box 12.6.[3,13,40,70] Some aspects of preoperative patient education and postoperative interventions are directed toward reducing the risks for a number of these complications.

Pulmonary Complications

The risk of pulmonary complications is highest during the early postoperative period. General anesthesia and use of pain medication increase the risk of this complication as does extended confinement to bed. Deep breathing exercises initiated on the day of surgery and early standing and ambulation may reduce the risk of pneumonia or atelectasis.

Deep Vein Thrombosis and Pulmonary Embolism

Although there is an increased risk of development of a deep vein thrombosis and a subsequent pulmonary embolism in all patients who have undergone surgery, this risk is particularly increased after total joint replacement surgery of

BOX 12.6 Potential Postoperative Complications

- Increased risk of pulmonary complications, including pneumonia or atelectasis
- Local or systemic infection
- Deep vein thrombosis or pulmonary embolism
- Delayed wound healing
- Muscle function deficits secondary to tourniquet compression and resulting ischemia or nerve compression
- Failure, loosening, or displacement of internal fixation devices
- Delayed union of bone after fracture, osteotomy, or joint fusion
- Rupture of incompletely healed soft tissue after repair or reconstruction
- Subluxation or dislocation of joint surfaces or implants
- Nerve entrapment from scar tissue formation resulting in pain or sensory changes
- Adhesions and scarring leading to contractures of soft tissues and joint hypomobility
- Loosening of joint implants secondary to periprosthetic osteolysis or infection

the hip or knee.[18,77] A therapist must be familiar with signs and symptoms and risk factors for these complications, as well as interventions for prevention or management. Therefore, the next section of this chapter contains more detailed information about deep vein thrombosis and pulmonary embolism.

Subluxation or Dislocation after Joint Surgery

If a joint capsule has been incised during surgery, as is the case for total joint replacement or a repaired labrum for a history of joint dislocation, there is an increased risk of postoperative dislocation. This risk can be reduced through patient education and exercise instruction. For example, a pre- or postoperative program typically includes teaching a patient proper use of a removable immobilization device, such as a splint or sling, and what positions to avoid during exercises and ADL.

Restricted Motion from Adhesions and Scar Tissue Formation

Movement of the operated area as early as possible after surgery with ROM exercises or continuous passive motion (CPM) within a safe range is directed at maintaining the extensibility of soft tissues as they heal and preventing postoperative contractures.

Failure, Displacement, or Loosening of Internal Fixation Device

Excessive or premature weight bearing prior to boney healing after open reduction and internal fixation of a fracture can cause loss of bone-to-bone apposition of the fracture site. Heavy lifting after a soft tissue repair in the upper extremity can cause rupture of sutured, but incompletely healed, tissues. Proper use of supportive devices, such as crutches or a walker, to control weight bearing during ambulation and appropriate progression of exercises and functional activities can reduce the risk of these postoperative complications.

Deep Vein Thrombosis and Pulmonary Embolism: A Closer Look

Lower extremity venous thrombosis can occur in the superficial vein system (greater or small saphenous veins) or the deep vein system (popliteal, femoral, or iliac veins) (Fig. 12.1).[32] A thrombus in one of the superficial veins in the calf usually is small and resolves without serious consequences.[66] In contrast, thrombus formation in a deep vein in the calf or more proximally in the thigh or pelvic region, known as a *deep vein thrombosis* (DVT), tends to be larger and can cause serious complications. When a clot breaks away from the wall of a vein and travels proximally, it is called an *embolus*. When an embolus affects pulmonary circulation, it is called a *pulmonary embolism*, which is a potentially life-threatening disorder.[32,66]

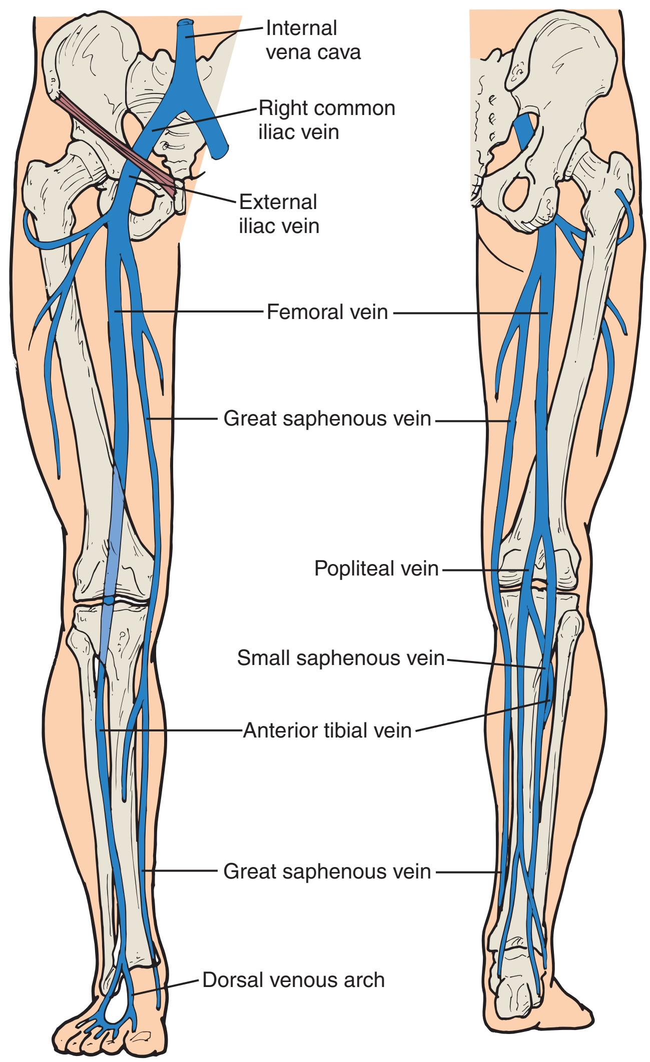

FIGURE 12.1 Veins of the lower extremity.

Risk Factors for DVT

A lower extremity DVT is a common complication after musculoskeletal injury or surgery, prolonged immobilization, or bed rest and is attributed to venous stasis, injury to and inflammation of the walls of a vein, or a hypercoagulable state of the blood.[35,76] Risk factors for DVT are listed in Box 12.7.[29,32,35,66]

Deep Vein Thrombosis: Signs and Symptoms

During the early stages of a DVT, only 25% to 50% of cases can be identified by clinical manifestations, such as dull aching or severe pain, swelling, or changes in skin temperature and color, specifically heat and redness.[2,32,35,66]

Although edema in the vicinity of the clot may be present, it may be too deep to palpate. If the clot is in the calf (distal DVT), nonspecific but constant pain in the knee region[29] or pain or tenderness of the calf may be felt with passive dorsiflexion of the affected foot (*Homans' sign*). However, the sensitivity of this test is poor and often reflects a false-negative or false-positive finding.[2,76] Only diagnostic imaging, such as ultrasonography, venous duplex screening, or venography, can confirm a DVT.[2,76]

Pulmonary Embolism: Signs and Symptoms

As described previously, pulmonary embolism is a possible consequence of DVT. Risk factors for pulmonary embolism are similar to those already identified for DVT (see Box 12.7).

The signs and symptoms of pulmonary embolism vary considerably depending on the size of the embolus, the extent of lung involvement, and the presence of coexisting cardiopulmonary conditions.[81] The hallmark signs and symptoms are a sudden onset of shortness of breath (dyspnea), rapid and shallow breathing (tachypnea), and chest pain located at the lateral aspect of the chest that intensifies with deep breathing and coughing. Other signs and symptoms include swelling in the lower extremities, anxiety, fever, excessive sweating (diaphoresis), a cough, and blood in the sputum (hemoptysis).[81]

BOX 12.7 Risk Factors for Deep Vein Thrombosis and Thrombophlebitis

- Postoperative or postfracture immobilization
- Prolonged bed rest
- Sedentary lifestyle or extended episode of sitting during long-distance travel
- Trauma to venous vessels
- Limb paralysis
- Active malignancy (within past 6 months)
- History of deep vein thrombosis or pulmonary embolism
- Advanced age
- Obesity
- Congestive heart failure
- Use of oral contraceptives
- Pregnancy

If a patient presents with signs or symptoms of possible pulmonary embolism, immediate medical referral is warranted for a definitive diagnosis and management.

Reducing the Risk of Deep Vein Thrombosis

Every effort should be made to reduce the risk of occurrence of a DVT and subsequent thrombophlebitis in patients who have undergone a surgical procedure, particularly a lower extremity procedure. The following medical/pharmacological and exercise-related interventions are implemented for risk reduction.[18,38,76,77]

- Prophylactic use of anticoagulant therapy (high molecular weight heparin) for the high-risk patient (e.g., the patient who has undergone lower extremity surgery or who is on bed rest)
- Elevating the legs when lying supine or when sitting
- No prolonged periods of sitting, especially for the patient with a long-leg cast
- Initiating ambulation as soon as possible after surgery, preferably no more than a day or two postoperatively
- Active "pumping" exercises (active dorsiflexion, plantarflexion, and circumduction of the ankle) regularly throughout the day when lying supine
- Use of compression stockings to support the walls of the veins and minimize venous pooling
- Use of a sequential pneumatic compression unit for patients on bed rest

CLINICAL TIP

In addition to medical/pharmacological management with administration of early postoperative, anticoagulant drugs,[18,77] one minute of active ankle pumping exercises performed at regular intervals during the day has been shown to increase venous blood flow (for up to 30 minutes after exercise) and decrease venous stasis in the calf after total hip replacement surgery.[54] Therefore, ankle pumping exercises are thought to decrease the risk of developing a DVT. Early ambulation (before day 2) after surgery also promotes circulation and reduces the risk of a DVT.[77]

Management of Deep Vein Thrombosis

Acute care management. If the presence of DVT and resulting thrombophlebitis is confirmed, immediate medical intervention is essential to reduce the risk of pulmonary embolism. Initial management includes administering anticoagulant medication, placing the patient on complete bed rest, elevating the involved extremity, and using graduated compression stockings. The reported time frame for bed rest varies from 2 days to more than a week.[1] Box 12.8 summarizes the guidelines for management of acute DVT and thrombophlebitis.[1,49]

During the period of bed rest, exercises usually are contraindicated because movement of the involved extremity

BOX 12.8 MANAGEMENT GUIDELINES—
Deep Vein Thrombosis and Thrombophlebitis

Structural and Functional Impairments

Dull ache or pain usually in the calf
Tenderness, warmth, and swelling with palpation

Plan of Care	Interventions
1. Relieve pain during the acute inflammatory period.	1. Bed rest, pharmacological management (systemic anticoagulant therapy); elevation of the affected lower extremity, keeping the knee slightly flexed.
2. As acute symptoms subside, regain functional mobility.	2. Graded ambulation with legs wrapped in elastic or nonelastic bandages or when pressure-gradient support stockings are worn.
3. Prevent recurrence of the acute disorder.	3. Continuation of appropriate medical and pharmacological management. Use of strategies to prevent DVTs.

CONTRAINDICATIONS: Passive or active motion or application of moist heat; use of a sequential pneumatic compression pump.

PRECAUTIONS: Following discharge but while continuing anticoagulant medication, avoid contact sports and high fall risk physical activities

may cause pain and is thought to increase congestion in the venous channels when tissues are inflamed. However, the optimal timing of when it is prudent to discontinue bed rest and resume ambulation after initiating anticoagulant therapy is in question.

FOCUS ON EVIDENCE

Aldrich and colleagues[1] conducted a systematic review of the literature to determine when a patient with DVT should be allowed to begin walking. The review revealed a limited number of studies (a total of five, three of which were randomized, controlled trials) that addressed this issue. Results of these studies suggest that early ambulation, begun within the first 24 hours after initiating anticoagulant therapy, does not increase the incidence of pulmonary embolism in patients without an existing pulmonary embolism and who have adequate cardiopulmonary reserve. However, if a patient has a known pulmonary embolism, an ambulation program must be initiated more cautiously. It is important to note that in the studies reviewed all patients who participated in an early ambulation program wore compression garments.

The results also revealed that early ambulation is associated with more rapid resolution of pain and swelling. The authors of the review were unable to identify studies that investigated the initiation and progression of other forms of exercise for patients with DVT.

Posthospitalization precautions. Following discharge, a patient typically continues on an anticoagulant medication (Coumadin) for about 6 months. During that time period, the patient must avoid contact sports, running, and skiing; however, treadmill walking or jogging and use of an elliptical trainer is permitted. Mandatory helmet use also is advisable during participation in high "fall risk" activities.[29]

Overview of Common Orthopedic Surgeries and Postoperative Management

Surgical management of musculoskeletal conditions encompasses many operative procedures and combinations of procedures involving a variety of tissues and structures, including muscles, tendons, joint capsules, cartilage, ligaments, fascia, nerves, and bones. Orthopedic surgery procedures can be divided into several broad categories, including repair, reattachment, reconstruction, stabilization, replacement, realignment, transfer, release, resection (excision), fixation, and fusion.[16,33,69] Examples of specific procedures in these categories are identified in Table 12.1.

The purpose of this final section of the chapter is to provide brief descriptions of some surgical procedures in these categories and a broad overview of the place of therapeutic exercise in postoperative rehabilitation. Chapters 17 through 22

TABLE 12.1 General Methods and Examples of Musculoskeletal Surgeries

Surgical Methods	Examples of Procedures
Repair	Tenorrhaphy, tendon repair; meniscus or ligament repair; articular cartilage repair
Release or decompression	Myotomy, tenotomy, fasciotomy; capsulotomy; tenolysis; muscle-tendon lengthening; retinacular release; arthroscopic subacromial decompression
Resection or removal	Synovectomy, meniscectomy, capsulectomy; débridement and lavage; laminectomy; excision of soft tissue or boney neoplasms
Realignment or stabilization	Tendon transfer, tenodesis; extensor mechanism realignment; capsulorrhaphy, capsular shift; osteotomy
Reconstruction or replacement	Tenoplasty; capsulolabral reconstruction; ligamentous reconstruction; chondroplasty; arthroplasty
Fusion or fixation for boney union	Arthrodesis; open reduction with internal fixation

contain more extensive background and descriptions of selected surgical procedures and progressions of postoperative management for each region of the upper and lower extremities. For more detailed descriptions of specific surgeries and operative techniques for musculoskeletal conditions from the orthopedic surgeon's perspective, many textbooks and journals are available for reference.[16,30,33,53,60,71,78] In addition, to design and implement safe and effective postoperative exercise programs for individual patients, a therapist needs a clear understanding of the unique aspects of each patient's surgery. This information is available in the operative report in a patient's medical record and further obtained through close communication with the surgeon.

NOTE: In the general descriptions of various orthopedic surgical procedures found in this chapter, the duration of immobilization and the initiation, progression, and intensity of exercise vary according to differences in surgical technique, the philosophy of the surgeon, and the nature of each patient's responses during postoperative rehabilitation.

Surgical Approaches: Open, Arthroscopic, and Arthroscopically Assisted Procedures

Open Procedure

An open surgical procedure involves an incision of adequate length and depth through superficial and deep layers of skin, fascia, muscles, and joint capsule so the operative field can be fully visualized by the surgeon during the procedure.[52,69] The term *arthrotomy* is used to describe an open procedure in which the joint capsule is incised and joint structures are exposed. Open approaches are necessary for surgeries, such as joint replacement, arthrodesis, internal fixation of fractures, and for some soft tissue repairs and reconstruction, such as tendon or ligament tears. There is extensive disturbance of soft tissues during an open procedure that requires a lengthy period of rehabilitation while soft tissues heal.

Arthroscopic Procedure

Arthroscopy is used as a diagnostic tool and as a means of treating a variety of intra-articular disorders.[26,53,65,72] Arthroscopic procedures are typically performed on an outpatient basis and often under local anesthesia.

Arthroscopy involves several very small incisions (portals) in the skin, muscle, and joint capsule for insertion of an endoscope to visualize the interior of the joint by means of a camera. Miniature, motorized surgical tools are inserted through the portals and are used to repair tissues in or around the joint, remove loose bodies, or débride the joint surfaces. Arthroscopic techniques most often are used for surgical procedures at the shoulder and knee[52,53,65,72] but recently are being used for hip joint disorders.[26]

Procedures include ligament, tendon, and capsule repairs or reconstruction, débridement of joints, meniscectomy, articular cartilage repair, and synovectomy. Because the incisions for the portals are so small, there is minimal disturbance of soft tissues during arthroscopic procedures. Therefore, rehabilitation usually—but not always—can proceed more quickly than after an open procedure.

Arthroscopically Assisted Procedure

An arthroscopically assisted procedure uses arthroscopy for a portion of the procedure but also requires an open surgical field for selected aspects of the operative procedure.[52,53] This sometimes is referred to as a "mini-open" procedure.[28]

Use of Tissue Grafts

In a number of orthopedic procedures to repair damaged structures, tissue grafts are implanted during the repair process. For example, soft tissue grafts are routinely used to reconstruct ligaments of the knee or ankle. Grafts are also used in articular cartilage repair procedures and many boney procedures.

Types of Grafts

Tissue grafts can be placed into several categories: autografts, allografts, and synthetic grafts.[46]

Autograft. An autograft, also referred to as an autogenous or autologous graft, uses a patient's own tissue harvested from a donor site in the body. Patellar tendon grafts, for example, have been used for more than four decades for intra-articular anterior or posterior cruciate ligament reconstruction.[63] More recently, autografts have been used for osteochondral implantation for repair of small, localized articular defects of the femoral condyles.[17]

Allograft. An allograft uses fresh or cryopreserved tissue that comes from a source other than the patient, typically from a cadaveric donor. This type of graft is used when an autograft in a previous surgery has failed or when an appropriate autograft is not available.

Synthetic grafts. Materials such as Gore-Tex® and Dacron offer an alternative to human tissue and have been used on a limited basis for ligament reconstruction in the knee. However, synthetic ligaments, to date, have had a high rate of failure and have not held up well over time.[17] Implantation of synthetic ligaments has also been associated with chronic synovitis of the knee.

The risks and drawbacks associated with autografts and allografts are summarized in Box 12.9.

Repair, Reattachment, Reconstruction, Stabilization, or Transfer of Soft Tissues

Surgical repair, reattachment, or reconstruction of soft tissues may be necessary after severe injury of a muscle, tendon, or ligament.[33,43,50,56] Surgical reconstruction and stabilization of a joint capsule may be indicated to reduce excessive capsular laxity contributing to instability of the joint.[51,79] Transfer of a muscle-tendon unit may be required to improve stability of an unstable joint or to enhance neuromuscular control and function.

Although there are numerous surgeries that fall into this category, a therapist must always consider the effects of immobilization and remobilization and the characteristics of healing of the types of soft tissue involved when designing a postoperative exercise program.

BOX 12.9 Risks with Use of Autografts and Allografts

Autografts
- Necessitates two surgical procedures for the patient
- Damage to or weakening of otherwise healthy tissue at the donor site

Allografts
- Potential disease transmission from the donor
- Decreased graft strength as the result of sterilization
- Greater risk of graft failure due to immunological rejection
- Insufficient availability of cadaveric tissues due to limited resources
- Not an option for articular cartilage implantation because cryopreservation destroys articular chondrocytes

Muscle Repair

A complete tear or rupture of a muscle is unusual, but it may occur if a muscle that is already in a state of contraction takes a direct blow or is forcibly stretched.[16]

Procedure

Immediate surgical repair of a severe tear or even complete rupture of a muscle is uncommon, because inflammation affects the texture of muscle tissue, making it difficult to hold sutures in place. A patient can achieve a more satisfactory outcome with a late repair (approximately 48 to 72 hours after injury) after acute symptoms have decreased. The muscle is reopposed, sutured, and immobilized so it is initially held in a shortened position as it begins to heal.[56,69]

Postoperative Management

- Muscle-setting exercise of the sutured muscle may be initiated immediately after surgery.
- When the immobilization is removed, active ROM, emphasizing controlled motion within a protected range, may be started to regain joint mobility and prevent contractures.
- Weight bearing is partially restricted until the patient achieves a functional level of strength and flexibility in the repaired muscle.
- Low-load, high-repetition resistance exercises are progressed very gradually to protect the healing muscle and should not elicit pain.
- Vigorous stretching or return to a full level of activity are contraindicated until soft tissue healing is complete—as long as 6 to 8 weeks postoperatively.

Tendon Repair

When a tendon tears or ruptures in a young person, it is usually the result of severe trauma.[62] In an elderly person with a history of chronic impingement, it is usually the result of progressive deterioration of a tendon coupled with a sudden, unusual motion.[6] Tendons usually rupture at musculotendinous or tendo-osseous junctions.[62] Common sites of acute tear or rupture are the bicipital tendon at the shoulder or the Achilles tendon.[44]

In patients with chronic tenosynovitis (paratendonitis) of the hand and wrist, the extensor tendons can erode over time and may eventually rupture along the dorsum of the hand.[7,13] The superficial tendons of the hand and foot also are vulnerable to injuries, particularly lacerations, that may require surgical repair. The flexor tendons of the fingers, for example, are commonly severed as the result of a deep laceration to the palm of the hand.

Aside from the acute pain that occurs at the time of injury to a tendon, a complete tear, rupture, or laceration causes loss of the ability to generate tension in the muscle-tendon unit and results in weakness but little pain. With a partial tear, there is significant pain during an active muscle contraction or stretch of the muscle-tendon unit.

Procedure

A complete tear or laceration of a tendon should be repaired immediately or within a few days after injury. Otherwise, the tendon begins to retract, making reattachment difficult. After the tendon is sutured, the repaired muscle-tendon unit is maintained in a shortened position, as with a complete tear of a muscle. A longer immobilization period may be required for a repaired tendon than for a repaired muscle because the vascular supply to tendons is poor.[23,27] However, remobilization involving a limited degree of tensile forces on the repaired tendon, is initiated as early as possible to prevent or minimize adhesions that can hinder tendon gliding.

Postoperative Management

- Muscle setting is begun immediately after surgery to prevent adhesions of the tendon to the sheath or surrounding tissues and to promote alignment of healing tissue. If it is possible to remove the immobilization for brief periods of exercise, passive motion or active contraction of a muscle group that is an antagonist of the repaired muscle tendon within a protected range also may be permissible within a few days after surgery.[7,14]
- Controlled antigravity motions are initiated after the repaired tendon has had several weeks to heal.
- Weight bearing may be restricted after an upper or lower extremity tendon repair, and heavy lifting activities are often contraindicated for as long as 6 to 8 weeks after an upper extremity repair.
- Because the muscle-tendon unit must be held in a shortened position for several weeks, regaining full range may be difficult. However, vigorous stretching and high-intensity resistance exercise should not be initiated until at least 8 weeks, when healing of the tendon has occurred.[14]

NOTE: For detailed information on postoperative rehabilitation after repair of tendons in the shoulder, fingers, or ankle, refer to Chapters 17, 19, and 22, respectively.

Ligament Repair or Reconstruction

After a large or complete tear of a ligament or when a ligament cannot be approximated for healing through closed reduction, surgical intervention through repair or reconstruction is warranted. Repair involves approximating and suturing the torn ligament, whereas reconstruction is accomplished with a tissue graft taken from a donor site. The knee, ankle, and elbow joints are the more common sites of injury and surgical intervention.[30,43,45,78]

Procedures

There are many surgical procedures that involve ligamentous repair or reconstruction. What is common to these surgeries is that, postoperatively, the joint is held in a position that places a safe level of tension on the sutured or reconstructed ligament during the healing process.[45,50] The duration of immobilization varies with the site and severity of injury and the type of repair or reconstruction that was done.[11,15,69,78]

Postoperative Management

Rehabilitation after ligament surgery emphasizes early but protected motion and progressive strengthening and weight-bearing activities to load the healing tissues consistently but safely.[45,63,78] How quickly the rehabilitation program is progressed depends on many factors, such as the type of repair or reconstruction that was done. For example, rehabilitation after anterior cruciate ligament (ACL) reconstruction utilizing a patellar tendon graft and bone-to-bone fixation can be progressed more rapidly than after a soft tissue stabilization procedure involving a hamstrings graft to stabilize the knee.[15,24,50] The rate of advancement also depends on the site of the repair or reconstruction. For example, support should be worn and weight bearing restricted for an extended period of time if the repair is at a potentially unstable joint and until muscular control can adequately protect the joint.

Generally, postoperative rehabilitation after ligamentous surgery is a lengthy process. For patients wishing to return to high-demand work or sports activities, it may take at least 6 months or as long as a year of rehabilitation.[24,50]

NOTE: Rehabilitation after reconstruction of ligaments of the knee and ankle is addressed in Chapters 21 and 22.

Capsule Stabilization and Reconstruction

A joint capsule with excessive laxity cannot act as a source of restraint to maintain appropriate stability of the joint. In turn, hyperlaxity of the capsule can be an underlying cause of symptomatic instability of a joint, ranging from subluxation to gross instability and recurrent dislocation. Joints particularly vulnerable to instability are those with little inherent stability, most notably the glenohumeral joint.

In some instances, an individual is predisposed to joint instability because capsular laxity and joint hypermobility are congenital, affecting many joints in the body. More often, joint instability is caused by an acute capsular injury as the result of traumatic dislocation or by progressive joint laxity as the result of repetitive stresses applied to the capsule when the joint is in extreme positions.[51] The latter is seen most often in athletes participating in sports, such as baseball and tennis, that involve repetitive, end-range shoulder motions.[74]

Surgical stabilization or reconstruction of a joint capsule is indicated for a patient with traumatic dislocation with associated capsular or labral avulsion or fracture, recurrent dislocation or symptomatic subluxation despite a course of nonoperative treatment, or an irreducible (fixed) dislocation.[51,65,74,82]

Procedures

Surgical procedures designed to reduce capsular laxity and joint volume and restore or improve joint stability fall into several categories and are performed using an open or an arthroscopic approach. An open procedure, necessitating an arthrotomy, is used if an open reduction of the joint is required or if there is extensive damage to the labrum, avulsion of the capsule, or a fracture. An arthroscopic approach typically is used to reduce capsular laxity and for some reconstructive procedures.[51,82]

Examples of stabilization and reconstruction procedures at the glenohumeral joint used for anterior, posterior, inferior, or multidirectional instabilities include the following.

Capsulorrhaphy (capsular shift). For capsulorrhaphy, using an arthroscopic or an open approach, a specific portion of the capsule is incised and tightened by imbrication/plication (overlapping and then suturing) of the redundant tissue.

Capsulolabral reconstruction. Capsulolabral reconstruction involves arthroscopic or open repair of a capsular lesion and labral tear (e.g., a Bankart lesion as the result of a traumatic anterior dislocation) by reattaching the labrum to the rim of the glenoid combined with stabilization of the capsule.

Electrothermally assisted capsulorrhaphy. For electrothermally assisted capsulorrhaphy, using an arthroscopic approach, thermal energy (laser or radiofrequency) is delivered to the capsule to shrink selective portions.[79]

Postoperative Management

After any joint stabilization or reconstruction procedure, the emphasis of postoperative management is to restore a balance of joint stability and functional motion while protecting the joint capsule and other repaired tissues during healing. The duration of the immobilization period and the selection and progression of postoperative exercises and functional activities depend, in part, on the preoperative direction of the instability, the surgical approach, the type of stabilization or reconstruction procedure and tissue fixation, and the quality of the patient's tissue.

Postoperative exercise focuses on the following.

- To restore ROM, initially active motions are emphasized within a protected range during early rehabilitation. Movements that place stress on the portion of the capsule that was tightened or repaired are progressed cautiously.
- When strengthening exercises are permissible, emphasis is placed on strengthening the dynamic stabilizers of the joint.

NOTE: Detailed progressions of postoperative exercises after surgical stabilization of the shoulder are presented in Chapter 17.

Tendon Transfer or Realignment

The transfer or realignment of a muscle-tendon unit alters the line of pull, potential force generation, and excursion of a muscle.[64] This may be indicated, for example, to improve the stability of an unstable shoulder joint or to stabilize a chronically dislocating patella. Although a realignment procedure slightly alters the line of pull, it does not change the action of the muscle-tendon unit. For instance, after an extensor mechanism realignment for recurrent patellar dislocation, the quadriceps remain an extensor of the knee.

A tendon transfer from one boney surface to another is sometimes indicated for a patient with a significant neurological deficit to prevent deformity and improve functional control.[64] With this type of procedure, not only is the line of pull of the muscle-tendon unit altered, the action of the muscle also is changed. For example, transfer of the distal attachment of the flexor carpi ulnaris to the dorsal surface of the wrist changes the action of the muscle-tendon unit from a flexor to an extensor of the wrist. This procedure may be indicated for a child with cerebral palsy to prevent wrist flexion contracture and improve active wrist extension for functional grasp.[64]

Procedures

During a tendon transfer or realignment procedure, usually the distal attachment of the muscle-tendon unit is removed from its boney insertion and reattached to a different bone, to a different location on the same bone, or to adjacent soft tissues.[56,64,69] The muscle-tendon unit is then immobilized in a shortened position for a period of time.

Postoperative Management

- As with a tendon repair, early muscle setting and protected motion are important to maintain tendon gliding. Resisted movements are progressed cautiously and gradually to protect the reattached tendon.
- If the purpose of the transfer was to change the function of the muscle, biofeedback and electrical muscle stimulation often are used to help a patient learn to control the new action of the transferred muscle-tendon unit.[69]

NOTE: Rehabilitation after tendon transfer for rheumatoid arthritis of the hand and wrist is described in Chapter 19. Chapter 21 contains information on rehabilitation after realignment of the patellar tendon for chronic patellofemoral dysfunction.

Release, Lengthening, or Decompression of Soft Tissues

Soft tissues may be incised or sectioned to improve ROM, prevent or minimize progressive deformity, or relieve pain. Procedures include myotomy, tenotomy, or fasciotomy.[11,56,69]

Surgical release of soft tissues may be indicated for a young patient with severe arthritis and resulting contractures in whom joint replacement is not advisable or as a preliminary procedure in adults prior to joint replacement.[13] Releases are also performed in patients with myopathic and neuropathic diseases, such as muscular dystrophy and cerebral palsy, to improve functional mobility.[69] Release of soft tissues to achieve decompression of tissues and relieve pain may be indicated for a patient with an impingement or compartmental syndrome, such as shoulder impingement or carpal tunnel syndrome.[11,56]

Procedures

During release or lengthening of a shortened muscle group, a portion of the muscle-tendon unit is surgically sectioned and fibrotic tissues are incised. A tendon also can be partially incised, as in a Z-lengthening to allow greater extensibility. The incised structures are then immobilized in a lengthened position except during exercise.[56,69] Some form of splinting or bracing in the corrected position in conjunction with exercise is always used postoperatively to maintain the gained ROM.

During decompression procedures, fasciae that are causing pressure on muscles, tendons, or nerves may be released or removed. Some decompression procedures, for example at the shoulder, also involve removal of osteophytes or alteration of boney structures that are creating excessive pressure on soft tissues.

Postoperative Management

- CPM and/or active-assistive ROM typically is initiated within a day or two after surgery. As soft tissue healing progresses, this is followed by active ROM through the gained ranges.[11,69]
- Strengthening of the antagonists of the lengthened muscle and use of the gained ROM during functional activities also are started early to maintain active control of movement within the newly gained range.

Joint Procedures

Orthopedic surgery involving the joints of the upper and lower extremities is performed most frequently for management of pain and dysfunction associated with arthritis or acute injury, such as a labral tear in the hip or shoulder joint. Surgical interventions for arthritis range from arthroscopic débridement and lavage of a joint or repair of a small chondral lesion to total joint replacement arthroplasty or joint fusion. An overview of stabilization and reconstruction procedures for the joint capsule was discussed earlier in this section of the chapter.

Arthroscopic Débridement and Lavage

Débridement and lavage of a joint involves arthroscopic removal of fibrillated cartilage, unstable chondral flaps, and loose bodies (fragments of cartilage or bone) in a joint.[13] Osteophytes also may be excised. This procedure is most often indicated to relieve joint pain and biomechanical "catching" during joint movement.

Synovectomy

Synovectomy involves removal of the synovium (lining of the joint) in the presence of chronic joint inflammation. Typically, it is performed in patients who have rheumatoid arthritis with chronic proliferative synovitis but minimal articular changes.[13,37,55,80] It is indicated if medical management has failed to alleviate joint inflammation for 4 to 6 months.

Procedure

Synovectomy of a joint is usually performed using an arthroscopic approach and is most commonly performed on the knee, elbow, wrist, and metacarpophalangeal (MCP) joints.[7,13,37,55,80] When synovium proliferates in the synovial sheaths of tendons, it is referred to as tenosynovitis. Removal of excessive synovium from tendon sheaths is known as a tenosynovectomy. This procedure is most often done for chronic synovitis of the wrist to clear synovium from the extensor tendons of the hand and, as such, is also called a dorsal clearance procedure.[13,55,80]

Although synovium tends to regenerate, resection of the inflamed synovium temporarily relieves pain and swelling and is thought to protect articular cartilage or tendons from enzymatic damage.[13,37]

Postoperative Management

- If an arthroscopic approach is used, passive or assisted ROM exercises (or CPM) and muscle-setting exercises are begun immediately or within 24 to 48 hours after surgery. Exercises quickly progress to active ROM. After synovectomy of the knee, for example, partial weight bearing as tolerated during ambulation progresses to full weight bearing by 10 to 14 days. After wrist or elbow synovectomy, lifting heavy objects is restricted for several weeks.
- After open synovectomy, progression of exercises and ADL proceeds more slowly.
- Progression of the rehabilitation program is based on the patient's response to exercise as well as the overall response to medication for the primary inflammatory disease. Every effort should be made to avoid excessive exercise or activity that could increase joint pain or swelling.[7,55,80]

Articular Cartilage Procedures

Surgical intervention for repair of articular cartilage defects (osteochondral lesions) has proven to be particularly challenging because of the limited capacity of this type of connective tissue to heal.[17,58] However, several procedures for a symptomatic extremity joint have been developed for this purpose. Selection criteria for one procedure over another are based on the size of the chondral lesion and patient-related factors, such as age and the ability to participate in the rehabilitation process.

Procedures

Abrasion arthroplasty, subchondral drilling, and microfracture. Several arthroscopic procedures are used to promote healing of small chondral defects in symptomatic joints through stimulation of a marrow-based repair response leading to local ingrowth of cartilagenous repair tissue (fibrocartilage).[17,58,72] Lesions of the medial femoral condyle and the posterior aspect of the patella are most often treated with one of these procedures.

Abrasion arthroplasty, also known as abrasion chondroplasty, and subchondral drilling involve abrasion or drilling of an articular surface to the superficial layer of subchondral bone with a motorized, arthroscopic burr or drill. The positive effects of these procedures have been questionable, at best, and possibly no more effective for symptom relief than arthroscopic débridement alone.[17]

NOTE: Although rehabilitation after abrasion arthroplasty or subchondral drilling is quite protracted, the benefits appear to be short-lived, because the fibrocartilage replacement tissue lacks the qualities of hyaline cartilage and therefore, tends to deteriorate readily after ingrowth.[11,17]

A newer technique, microfracture of articular cartilage, is designed for repair of very small osteochondral defects

(<1.5 cm^2). This procedure involves the use of a nonmotorized arthroscopic awl to penetrate the subchondral bone systematically and expose the bone marrow. Initial studies of this procedure suggest that microfracture relieves symptoms more effectively than abrasion arthroplasty or subchondral drilling, possibly because use of a nonmotorized instrument reduces the potential for tissue damage due to thermal necrosis.[17,58]

Chondrocyte transplantation. Chondrocyte transplantation, also known as autologous chondrocyte implantation,[31,58] is designed to stimulate growth of hyaline cartilage for repair of focal defects of articular cartilage and prevention of progressive deterioration of joint cartilage leading to osteoarthritis.[12,17,31,57,58] It was introduced as an alternative to abrasion arthroplasty during the mid-1990s for full-thickness, symptomatic focal chondral and osteochondral defects (2.5 to 4.0 cm^2) of the knee, specifically lesions of the femoral condyles or patella.[12]

Chondrocyte transplantation occurs in two stages. First, healthy articular cartilage is harvested arthroscopically from the patient. Chondrocytes are extracted from the articular cartilage, cultured for several weeks, and processed in a laboratory to increase the volume of healthy tissue. The second phase is the implantation phase, which currently requires arthrotomy (open procedure). After the chondral defect sites are débrided and covered with a periosteal patch, millions of autologous chondrocytes are injected under the patch and into the articular defect.[17]

Osteochondral autografts and allografts. Unlike transplantation of chondrocytes, ostechondral grafts involve transplantation of intact articular cartilage along with some underlying bone, resulting in a bone-to-bone graft.[58] Several procedures fall within this category. An autogenous osteochondral graft (an autograft) procedure harvests a patient's own articular cartilage from a donor site.[17] As noted previously (see Box 12.9), a drawback to this type of articular graft is damage to the donor site, specifically the creation of an osteochondral defect at the donor site. To lessen concerns about damage to a patient's articular donor site, osteochondral mosaicplasty was developed.[9] During this procedure, small-diameter osteochondral plugs are retrieved from a donor site and press-fit into the chondral defect.

In contrast, an osteochondral allograft procedure transplants intact articular cartilage from a cadaveric donor. However, only fresh, intact grafts, which are in limited supply and can be stored for only a few days, can be used. This is because freezing the graft material prior to storage for later use destroys the articular chondrocytes, thus causing graft failure.

Postoperative Management

Rehabilitation after all of the articular cartilage procedures described in this section, with the exception of arthroscopic débridement, is a slow and arduous process.[12,17,31,39,57,58] Exercise is an important aspect of postoperative management at each stage of rehabilitation. Early passive motion, sometimes with CPM, and protected weight bearing are essential to promote the maturation and maintain the health of implanted chondrocytes or an osteochondral graft. Full weight bearing is allowable by 8 to 9 weeks. A well controlled program of progressive exercises continues for 6 months to a year to achieve optimal functional outcomes.[31,39]

NOTE: More detailed information on rehabilitation after procedures to repair articular cartilage and osteochondral lesions is presented in Chapter 21.

Arthroplasty

Any reconstructive joint procedure, with or without joint implant, designed to relieve pain and improve function is referred to broadly as arthroplasty. This definition encompasses several categories of arthroplasty.

Procedures

Excision arthroplasty. Excision arthroplasty, also known as resection arthroplasty, involves removing periarticular bone from one or both articular surfaces. A space is left in which fibrotic (scar) tissue is laid down during the healing process.[13,55] Excision arthroplasty has been performed in a variety of joints, including the hip, elbow, wrist, and foot, to alleviate pain. Although an old procedure and less frequently used now than in the past, this type of arthroplasty is still considered appropriate in select cases. Resection of the head of the radius for late-stage arthritis of the humeroradial joint[19] or a severe comminuted fracture of the radial head[59] and resection of the distal ulna (Darrach procedure) for late-stage arthritis of the distal radioulnar joint[21] are still used as primary procedures to reduce pain. However, excision arthroplasty of the hip (Girdlestone procedure) now is used only as a salvage procedure, for example, after a failed total hip replacement when revision arthroplasty is not feasible.[13]

Despite the usefulness of excision arthroplasty, there are also a number of disadvantages.

- Possible joint instability
- In the hip, significant leg length discrepancy and poor cosmetic result because of shortening of the operated extremity
- Persistent muscular imbalance and weakness

NOTE: Rehabilitation after excision arthroplasty of the radial head is discussed in Chapter 18.

Excision arthroplasty with implant. For excision arthroplasty with implant, after removing the articular surface, an artificial implant is fixed in place to help in the remodeling of a new joint. This is sometimes called implant resection arthroplasty.[19,55] The implant usually is made of a flexible silicone material and becomes encapsulated by fibrous tissue as the joint reforms.

Interposition arthroplasty. Interposition arthroplasty essentially is biological resurfacing of a joint to provide a new articulating surface. After the involved joint surface is débrided, a foreign material is placed (interposed) between the two joint surfaces.[5,55] A variety of materials may be used to cover the joint surface, including fascia tendon, silicone material, or metal.

This type of arthroplasty is used most often in young patients with incapacitating pain and loss of function, resulting from severe deterioration of an articular surface in whom joint replacement arthroplasty is not appropriate. Some examples of interpositional arthroplasty are resurfacing of the glenoid fossa with fascia[5] and tendon interposition arthroplasty of the carpometacarpal (CMC) joint of the thumb.[20]

Joint replacement arthroplasty. Joint replacement arthroplasty includes total joint replacement arthroplasty and hemireplacement arthroplasty. Total joint replacement is a common reconstructive procedure to relieve pain and improve function in patients with severe joint degeneration associated with late-stage arthritis (Fig. 12.2).[13,52,55,60]

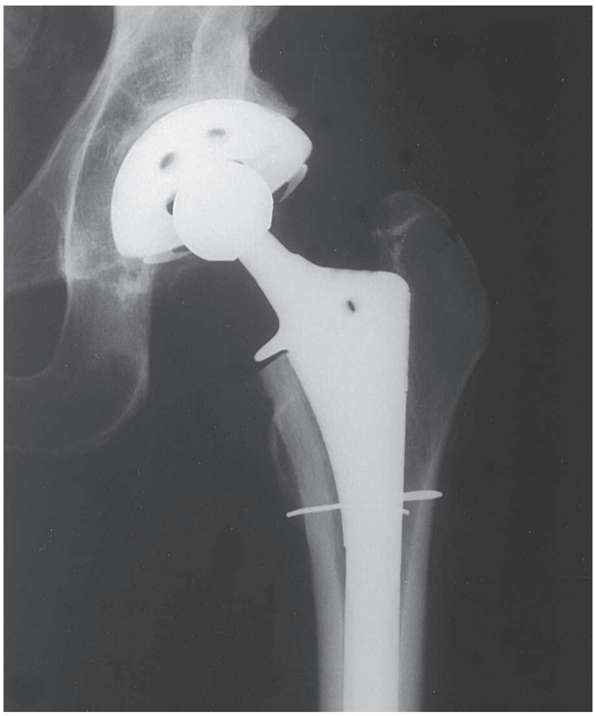

FIGURE 12.2 Total hip replacement arthroplasty. Both the acetabular and femoral portions of the joint have been replaced with prosthetic components. *(From McKinnis, LN: Fundamentals of Musculoskeletal Imaging, ed 3. Philadelphia: FA Davis, 2010, p 354, with permission.)*

Total joint replacement procedures involve resecting both affected articulating surfaces of a joint and replacing them with artificial components, whereas hemireplacement arthroplasty involves resection and replacement of just one of the articulating surfaces of a joint.[13,55,60] In addition to use for late-stage arthritis when only one articulating surface of a joint has deteriorated, hemireplacement is also an option after femoral neck and proximal humeral fractures.[13]

- ***Materials, designs, and methods of fixation.*** Prosthetic replacements have been developed and refined for almost every joint of the extremities but have been used more frequently and successfully at the hip and knee than in the smaller joints of the foot and hand.[13,55,60] The materials, designs, and methods of fixation used for joint replacement arthroplasty are summarized in Box 12.10. Prosthetic implants are made of inert materials, specifically metal alloys, high-density polyethylene (plastic) material, and sometimes ceramic material. Because the biomechanical features of each joint are unique, there are a multitude of prosthetic designs. Component designs range from unconstrained (resurfacing) with no inherent stability to semiconstrained and fully constrained (articulated) designs that provide stability to an unstable joint. In almost all designs, one articular surface is metal and the other is plastic. The choice of fixation is based, in part, on the anticipated loads that will be placed on the prosthetic implants over time. Cemented fixation, using an acrylic-based cement (polymethylmethacrylate), eventually tends to break down at the bone-cement interface, resulting in mechanical loosening of the implant and pain.[13,60,70] Therefore, cemented fixation is used primarily for older or sedentary patients who are unlikely to place high stresses on the implants. Bio-ingrowth fixation, a form of cementless fixation, is achieved by growth of bone into the porous-coated exterior surface of an implant. It is thought that this form of fixation, which is advocated for younger, more active patients, is less likely to loosen over time.[13,60,70] Most recently, a nonporous, cementless prosthetic implant has been developed that is used with a bioactive compound that stimulates bone growth. Fixation is achieved by a macrointerlock between the implant and adjacent bone.[60]

BOX 12.10 Materials, Designs, and Methods of Fixation for Joint Replacement Arthroplasty

Implant Materials
- Rigid: inert metal (cobalt-chrome alloy, titanium alloy, or ceramic)
- Semirigid: plastic (high-density polymers such as polyethylene)

Implant Designs
- Unconstrained (resurfacing): no inherent stability
- Semiconstrained
- Fully constrained (articulated): inherent stability

Methods of Fixation
- Cemented
  - Acrylic cement (polymethylmethacrylate)
- Noncemented
  - Biological fixation (microscopic ingrowth of bone into a porous-coated prosthetic surface)
  - Macrointerlock between a nonporous component and bone with a bioactive compound applied to the component to improve osseous integration
  - Press fit (tight fit between bone and implant)
  - Screws, bolts, or nails
- Hybrid
  - Noncemented component for one joint surface and cemented component for opposing joint surface

NOTE: Descriptions of implants are reviewed, joint by joint, in Chapters 17 through 22.

- ***Minimally invasive versus traditional arthroplasty.*** A recent advance in joint replacement arthroplasty that may have a significant impact on postoperative rehabilitation and outcomes is the development of minimally invasive surgical techniques with less disturbance of soft tissues than traditional arthroplasty. Currently, minimally invasive procedures are being used for total hip and total knee replacement.[4,10,75] Although traditional hip and knee replacement procedures have provided excellent results for several decades,[13,61,70] they impose substantial trauma to skin, muscles, and the joint capsule, leading to significant postoperative pain, which in turn affects the length of time required for postoperative recovery. Compared to surgical techniques used for traditional hip and knee replacement, minimally invasive procedures use smaller skin incisions, less muscle splitting to expose the joint, and less disruption to the capsule in preparation for insertion of prosthetic implants. For example, in a minimally invasive hip replacement, one or two small incisions (<10 cm in length) are used rather than a single incision (15 to 30 cm long involving extensive muscle splitting) that is typically used in a traditional hip replacement.[10] A 2-year follow-up indicates that patients who underwent minimally invasive total knee replacement had less pain, better early motion, and a shorter hospital stay than patients who had standard knee replacement surgery.[75] Research is ongoing to determine if the long-term results of minimally invasive procedures are equal to the long-term outcomes of traditional arthroplasty while enabling a patient to recover more rapidly after surgery, participate in accelerated rehabilitation, and return to full activity in less time.
- ***Contraindications to joint replacement arthroplasty.*** Despite the positive functional outcomes after joint replacement arthroplasty, not every patient with advanced joint disease is a candidate for these procedures. Contraindications are noted in Box 12.11.[13,55,60] Although opinions vary as to which of these contraindications are absolute versus relative, there is general agreement that infection is of the utmost concern.

BOX 12.11 Contraindications to Total Joint Arthroplasty

- Active infection in the joint
- Chronic osteomyelitis
- Systemic infection
- Substantial loss of bone or malignant tumors that prohibit adequate implant fixation
- Significant paralysis of muscles surrounding the joint
- Neuropathic joint
- Inadequate patient motivation

Postoperative Management

Postoperative management, including therapeutic exercise interventions, after selected types of joint replacement arthroplasty of major joints of the extremities is described in detail in Chapters 17 through 22.

Arthrodesis

Arthrodesis is surgical fusion of the surfaces of a joint. It is indicated as a primary surgical intervention in cases of severe joint pain associated with late-stage arthritis and joint instability in which mobility of the joint is a lesser concern.[8,73] Arthrodesis of the extremity joints is also reserved for patients with significant weakness of muscles surrounding a joint as the result of neurological abnormalities, such as a peripheral neuropathy of the ankle or a severe brachial plexus injury.[56,69] In addition, it may be the only salvage procedure available for a patient with a failed total joint arthroplasty when revision arthroplasty is not an option.[48]

Arthrodesis is used most frequently in the cervical or lumbar spine, wrist, thumb, and ankle but also has been used in select instances in the shoulder and hip. For example, arthodesis of one or more joints of the ankle and foot (Fig. 12.3) is the procedure most often used to relieve pain associated with severe arthritis.[73]

Optimal positions for arthrodesis are listed in Table 12.2. The optimal position is somewhat dependent on the functional needs or goals of each patient and may vary slightly in some joints, such as the elbow and ankle. For example, the optimal position for elbow fusion in the dominant upper extremity usually is between 70° and 90°. However, in the nondominant limb, the elbow must be in more extension for

FIGURE 12.3 Arthrodesis (surgical fusion with internal fixation of the ankle). *(From Logerstedt, DS, Smith, HL. Postoperative Management of the Foot and Ankle. Independent Study Course 15.2. Postoperative Management of Orthopedic Surgeries. Orthopedic Section. La Crosse, WI, APTA, Inc., 2005, with permission.)*

TABLE 12.2 Optimal Positions for Arthrodesis

Joint	Position
Shoulder	At 15°–30° of abduction and flexion and 45° of internal rotation: a position so the hand can reach the mouth
Elbow	Dominant upper extremity: 70°–90° of flexion and midposition of the forearm; nondominant limb: more extension for assisting during tasks
Wrist	Slight extension
MCP of the thumb	At 20° of flexion
Hip	At 10°–15° of flexion to allow ambulation and comfortable sitting
Ankle	
Tibiotalar joint	Neutral (90°) or slight equinus for women who wear low heels
Subtalar joint	Neutral to valgus
Spine	Neutral so normal lordosis or kyphosis is maintained

assistive activities.[8] For a woman, the optimal position for arthrodesis of the ankle might be in slightly greater plantarflexion than for a man to allow a woman to wear shoes with a slightly higher heel height.[69]

Although arthrodesis eliminates pain and creates stability in an involved joint, it is not without its disadvantages. Because loads are transferred to joints above and below the fused joint, there is the potential of developing excessive stresses leading to pain and hypermobility at those joints over time.

Procedure

Fusion of joint surfaces in the position of maximum function is achieved with internal fixation (i.e., pins, nails, screws, plates, bone grafts). Initially, the joint is immobilized in a cast above and below the site of arthrodesis for 6 to 12 weeks postoperatively. Later, an orthotic device is used until complete boney healing and ankylosis has occurred.[8]

Postoperative Management

- Because no movement is possible in the fused joint, ROM and strength must be maintained above and below the operated joint.
- Weight bearing is restricted until there is evidence of boney healing.

Extra-articular Boney Procedures

Two of the more common reasons for surgical intervention involving boney structures outside a joint are fractures that require open reduction combined with internal fixation and deformity or malalignment of bone, sometimes associated with arthritis.

Open Reduction and Internal Fixation of Fractures

Fractures are managed with either closed or open reduction. The process of bone healing and fracture management, addressed in Chapter 11, applies regardless of the method of reduction. In most instances in which open reduction is required, some type of internal fixation device is used to stabilize and maintain the alignment of the fracture site as it heals.

Procedures

During surgery after the fracture site is exposed, any number of internal fixation devices, such as pins, nails, screws, plates, or rods, may be used to align and stabilize the bone fragments.[16,69] Intertrochanteric fracture of the femur, for example, is commonly stabilized with a compression plate and screws, as shown in Figure 12.4. After a fracture has healed, a second surgery may be necessary to remove some or all of the internal fixation devices, which tend to migrate over time.

Postoperative Management

Maintaining stability of the fracture site so boney healing can occur and getting the patient up and out of bed as early as possible are the main priorities postoperatively. The progression of rehabilitation after surgical stabilization of a fracture is dependent not only on factors such as the type and severity of fracture and the patient's age and health status but also on the method(s) of internal fixation used.

Some fixation methods eliminate the need for external immobilization of the fracture site (e.g., with a cast), thereby enabling a patient to begin assisted or active movement of the involved limb and protected weight bearing shortly after surgery. With other fractures, however, external immobilization and restricted weight bearing are necessary even with the use of internal fixation.[16,69]

During postoperative management, not only must the fracture site be protected as it heals, soft tissues injured at the time the fracture occurred and further damaged when exposing the field during surgery must also be managed appropriately as they heal.

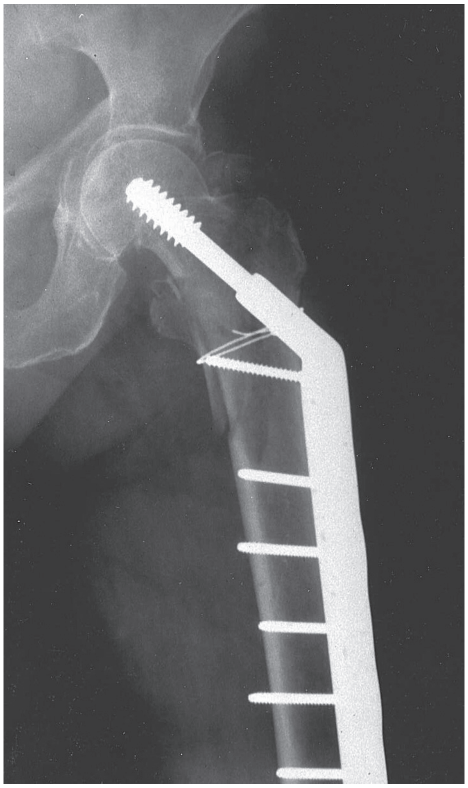

FIGURE 12.4 Intertrochanteric fracture of the left femur, fixed with compression plate and screws. *(From McKinnis, LN: Fundamentals of Musculoskeletal Imaging, ed 3. Philadelphia, FA Davis, 2010, p 65, with permission.)*

NOTE: Surgical interventions and postoperative management after hip fracture are discussed in Chapter 20.

Osteotomy

Osteotomy—the surgical cutting and realignment of bone—is an extra-articular procedure indicated for the management of impairments associated with a number of musculoskeletal disorders. It is most often performed at the knee or hip.[13] Osteotomy is used, for example, to reduce pain and correct deformity in selected patients, such as a young adult with moderate, focal articular degeneration in the medial compartment and a varus deformity of the knee as the result of osteoarthritis[36,55] or a child with severe hip joint deterioration and pain secondary to congenital dysplasia or Legg-Calvé-Perthes disease (avascular necrosis of the head of the femur).[56]

In both of these examples, cutting and realigning bone near the involved joint shifts weight-bearing loads to intact joint surfaces, thus reducing joint pain and reducing further deterioration of the involved articular cartilage.[13,69] It is also thought that redistributing loads on joint surfaces may stimulate the growth of fibrocartilage in the unloaded compartment of the joint.[22] A successful osteotomy delays the need for total joint replacement in patients who will most likely require revision arthroplasty sooner than the average patient with degenerative arthritis.

Osteotomy is also used to correct angular or rotational deformities of bone occurring in congenital or developmental disorders, such as congenital dislocation of the hip, acquired hip dislocation in cerebral palsy, or congenital foot deformities.[69] Osteotomy is also necessary for surgically shortening or lengthening a bone to correct a severe leg length discrepancy.[16,69]

Procedures

Numerous procedures are classified as osteotomies. Several examples are:

- High tibial, medial or lateral opening, wedge osteotomy with screw-plate fixation to correct a varus or valgus deformity, change the mechanical axis of the knee, and shift the load on joint surfaces in a patient with unicompartmental degenerative arthritis of the knee.[36,42]
- Medial wedge osteotomy of the distal femur to correct a valgus deformity of the knee and shift weight-bearing loads away from the deteriorated cartilage in the lateral compartment of the knee.[55]
- Intertrochanteric osteotomy of the proximal femur, which repositions the femoral head to change the area in which weight bearing occurs for a patient with arthritis or avascular necrosis of the hip.[55]
- Periacetabular osteotomy, which repositions the acetabulum, to improve coverage of the head of the femur for a patient with congenital dysplasia of the hip and recurrent dislocation that could not be managed effectively by nonoperative methods, such as splinting.[69]

During an osteotomy, muscles and other soft tissues may have to be reflected to expose the operative field and then reattached or repositioned. As with any type of soft tissue repair, muscle-tendon units disturbed during surgery must be protected from excessive stress postoperatively.

Postoperative Management

The primary concern of postoperative management is maintaining bone-to-bone apposition for healing of the osteotomy site. Some procedures allow early joint motion and protected weight bearing, because internal fixation maintains apposition of the osteotomy fragments. Others require additional external (cast) immobilization of the joints above and below the osteotomy site until boney union occurs, which may take as long as 8 to 12 weeks.[22,55] Full functional recovery after osteotomy may take as many as 6 months.

Postoperative exercises, when permissible, include the following.

- If immobilization in a cast is necessary, the patient can begin active ROM of the joints above and below the site of the osteotomy to prevent joint stiffness and undue muscle weakness.
- When motion and weight bearing are allowed, either immediately after surgery or when the cast is removed, active-assistive and active exercise progressing to light resistive exercise are performed to restore joint ROM and strength. (See discussion of management of fractures after immobilization in Chapter 11.)
- Weight bearing typically is protected for 4 to 6 weeks or more.

Independent Learning Activities

Critical Thinking and Discussion

1. You have been asked to develop a preoperative patient education program for a group of individuals who are scheduled to undergo either total hip or knee replacement arthroplasty. What topics should be covered in your presentation, and why are they important for prospective patients to understand?
2. You are seeing an elderly patient for the first time who yesterday underwent an open reduction with internal fixation of a fracture of the hip (proximal femur). What would be the priorities of your initial examination of this patient? What is the general emphasis of postoperative management, including goals and interventions, during the maximum, moderate, and minimum protection phases of postoperative rehabilitation?
3. What part does a program of exercise and physical activity play in the overall prevention or management of a DVT? What are the signs and symptoms of DVT that a patient at risk for this problem must learn to recognize? If you suspect that a patient you are seeing after some type of orthopedic surgery of the lower extremity has developed a DVT, what questions should you ask the patient? What should you do before contacting the patient's physician?
4. Briefly describe the various surgical interventions for repair of articular cartilage.
5. Differentiate among the following types of soft tissue or boney surgeries primarily used in the management of arthritis: arthrodesis, arthroplasty, articular cartilage repair, débridement, and osteotomy. Briefly describe each surgery and compare and contrast postoperative management with respect to the use of therapeutic exercise.
6. Discuss the similarities and differences of postoperative management of the following soft tissue surgeries: muscle repair, tendon repair, tendon transfer, ligament reconstruction, repair of a joint capsule, tenotomy or myotomy, and decompression procedures.

CHAPTER

13

Peripheral Nerve Disorders and Management

Therapeutic exercise and related manual therapy techniques would not be possible without the nervous system and all its components activating, controlling, and modifying motor responses as well as receiving and interpreting feedback from the variety of sensory receptors throughout the body. Because of their intimate proximity to all the structures in the trunk and extremities, nerves may become stressed or injured with various musculoskeletal conditions, postures, and repetitive microtraumas resulting in neurological symptoms, structural and functional impairments, activity limitations, and participation restrictions. Highlights of the anatomy and results of injury to the peripheral nervous system are reviewed in the first section of this chapter for the purpose of laying the foundation for management guidelines, including therapeutic exercise and manual therapy interventions, that are described in the remainder of the chapter. In the treatment of patients with musculoskeletal impairments, often the therapist does not think of the components of the central nervous system. Even though this chapter primarily deals with the peripheral nervous system, acknowledgment that the central nervous system plays a key role in the initiation and control of movement is a must. The reader is referred to Chapter 8 for consideration of motor control in the total rehabilitation of the individual.

The development of a plan of care and intervention techniques differs for patients with impairments due to nerve involvement. Nerve injuries may result in significant activity limitations and participation restrictions due to paralysis and resulting deformity. Utilizing the principles presented in this chapter, along with the knowledge and skills of examination and evaluation of the neural, muscular, and skeletal systems, the reader should be able to design therapeutic exercise programs for patients with limitations due to injury or mobility restrictions of the peripheral nervous system. Also included in this chapter is a section on complex regional pain syndromes type I (reflex sympathetic dystrophy) and type II.

Review of Peripheral Nerve Structure

Nerve Structure

Peripheral components of the neuromuscular system include the alpha and gamma motor neurons, their axons, and the skeletal muscles they innervate; the sensory neurons and their receptors located in the connective tissues, joints, and blood vessels; and the neurons of the autonomic nervous system. Connective tissue surrounds each axon (endoneurium) as well as fascicles (perineurium) and entire nerve fibers (epineurium).[48,69] The axolemma is the surface membrane of axon. Schwann cells lie between the axolemma and endoneurium; they form myelin, which functions to insulate the axon as well as speed the conduction of action potentials along the nerve fiber. The exceptions are very small fibers that are unmyelinated. A peripheral nerve may consist of a single fascicle or consist of several fascicles.[48] The structure of a peripheral nerve with its connective tissue and vascular layers is illustrated in Figure 13.1, and the location of their cell bodies is summarized in Box 13.1.

Mobility Characteristics of the Nervous System

Butler[10] described the peripheral and central nervous systems as a continuous tissue tract; simply stated, the tract is like an H on its side. Structurally and functionally, there is continuity of the connective tissues, the impulse transmission between the neurons, and the chemical flow of neurotransmitters. The system is designed to be mobile and deform, while at the same time conducting impulses.

When a joint moves and tension is placed on a nerve bed, nerve gliding is toward the moving joint (convergence); and when tension is relieved, nerve gliding is away from the moving joint (divergence). Initially, excursion of the nerve occurs adjacent to the moving joint, but excursion of the nerve progresses more distant from the moving joint as limb movement continues.[69]

Substantial mobility in the nervous system is needed for an individual to move during functional activities. With movement of an extremity, before there is increased tension in the nerve itself, the whole peripheral nerve moves, and there is movement between connective tissues and neural tissues. The mobility is allowed without undue stress on the nerve tissue because:

- The arrangement of the spinal cord, nerve roots, and plexes allows mobility. If any part of the H is placed under tension, the force can be dissipated throughout the system.

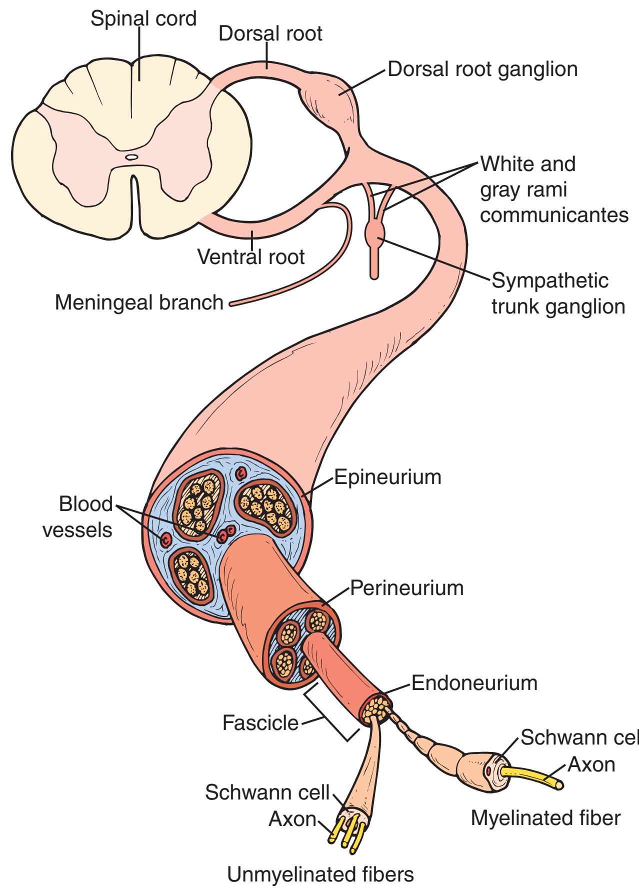

FIGURE 13.1 Peripheral nerve and its connective tissue coverings.

BOX 13.1 Content of Peripheral Nerves

Peripheral nerves contain a mix of motor, sensory, and sympathetic neurons.

- *Alpha motor neurons (somatic efferent fibers)*: cell bodies located in anterior column of spinal cord; innervate skeletal muscles
- *Gamma motor neurons (efferent fibers)*: cell bodies located in lateral columns of spinal cord; innervate intrafusal muscle fibers of the muscle spindle
- *Sensory neurons (somatic afferent fibers)*: cell bodies located in the dorsal root ganglia; innervate sensory receptors
- *Sympathetic neurons (visceral afferent fibers)*: cell bodies located in sympathetic ganglia; innervate sweat glands, blood vessels, viscera, and glands

- The nerves themselves are wavy and can straighten when tension is applied.
- The connective tissue around the individual nerves and bundles of nerves (epineurium, perineurium, endoneurium) absorb tensile forces before the nerve itself stretches.

Cadaveric and in vivo ultrasound studies of median nerve mobility and strain have shown nerve movement of 5 to 10 mm depending on the position and motion of each of the joints in the upper extremity and neck, as well as a wavy appearance when on a slack (unloaded) and a straightening of the nerve when under tension.[21] Strain calculated in the stretch position (see upper limb tension test for the median nerve described in the section on neural tension impairments) was 2.5% to 3.0%.[21]

Common Sites of Injury to Peripheral Nerves

Injury to the nerves of the peripheral nervous system can occur anywhere along the pathway from the nerve roots to their termination in the tissues of the trunk and extremities. As each nerve courses from the intervertebral foramina to its peripheral destination, there are sites that increase its susceptibility to either tension or compression. Symptoms and signs of nerve impairments are sensory changes or loss and motor weakness in the distribution of the involved nerve fibers. Because nerves are composed of innervated connective tissue and blood vessels surround the axons, ischemic pain or tension pain may also occur when these tissues are stressed. Also, because peripheral nerves include sympathetic fibers, autonomic responses might occur. Whenever neurological symptoms and signs are present, the entire nerve should be tested for mobility and signs of compression at key points along its pathway.

In this section, primary sites of compression, tension, or injury are identified for the peripheral nerves in the upper and lower quarter regions including their origins at the nerve roots and pathways through each of the plexuses.

Nerve Roots

Nerve roots emerge from the spinal canal and traverse the foramina of the spine, where they can become impinged as a result of various pathologies of the spine that reduce the space in the foramina, such as degenerative disc disease (DDD), degenerative joint disease (DJD), disc lesions, and spondylolisthesis. With reduced spinal canal or foraminal space (stenosis), extension, side bending, or rotation to the side of the stenosis further decreases the space where the nerve root courses and may cause or perpetuate symptoms. If adhesions place tension on a nerve root, nerve mobility tests (described later in this chapter) can reproduce symptoms when the spine is side-bent (laterally flexed) away from the side causing the symptoms. When involved, symptoms and signs include sensory changes and/or loss of motor function in the respective dermatome and myotome patterns (Fig. 13.2 and Box 13.2). Nerve roots of the upper quarter include C5 through T1 and those of the lower quarter L1 through S3. Management guidelines for individuals with nerve root symptoms are described in Chapter 15.

Brachial Plexus

After emerging from the foramina, the nerve fibers divide into anterior and posterior primary rami. Vasomotor fibers from the sympathetic trunk join the anterior primary rami to course within the brachial plexus and peripheral nerves to the extremities. The brachial plexus is formed by the anterior primary divisions of the C5–T1 nerve roots (Fig. 13.3). The plexus functions as the distribution center for organizing the contents of each peripheral nerve. In addition, Butler[11] suggested that the weave pattern in the brachial plexus contributes to the mobility of the nerves such that when tension is placed on any one peripheral nerve, the tension is transmitted to several cervical nerve roots rather than just one nerve root.

The brachial plexus courses through the region known as the thoracic outlet. There are three primary sites for compression or entrapment of the neurovascular structures in this region (see Fig. 13.19).

- Interscalene triangle, bordered by the scalenus anterior and medius muscles and first rib
- Costoclavicular space between the clavicle superiorly and the first rib inferiorly
- Axillary interval between the anterior deltopectoral fascia, the pectoralis minor, and the coracoid process
- Structural anomalies, such as a cervical rib or malunion of a clavicular fracture, may compress or entrap a portion of the plexus

When vascular and/or neurological symptoms are caused by impairments in the thoracic outlet, it is commonly referred to as thoracic outlet syndrome. Characteristics of this syndrome and management guidelines are described later in the chapter.

Other injuries to the brachial plexus include:

- **Upper plexus injuries (C5, 6):** The most common injury to the plexus involves compression or tearing of the upper trunk. The mechanism involves shoulder depression and lateral flexion of the neck to the opposite side. There is loss of abduction and lateral rotation of the shoulder and weakness in elbow flexion and forearm supination (waiter's tip position). Erb's palsy occurs with birth injuries when the shoulder is stretched downward, although Benjamin[6] cautioned that there are maternal and infant factors that could contribute to this injury in addition to the forces applied during delivery. A "stinger" occurs with injuries that might be sustained when a football player lands on the upper torso and shoulder with the head/neck laterally flexed in the opposite direction.
- **Middle plexus injuries (C7):** Rarely seen alone.
- **Lower plexus injuries (C8, T1):** Usually due to compression by a cervical rib or stretching the arm overhead. Klumpke's paralysis (paralysis of the intrinsics of the hand) occurs in birth injuries when the baby presents with its arm overhead.[6]

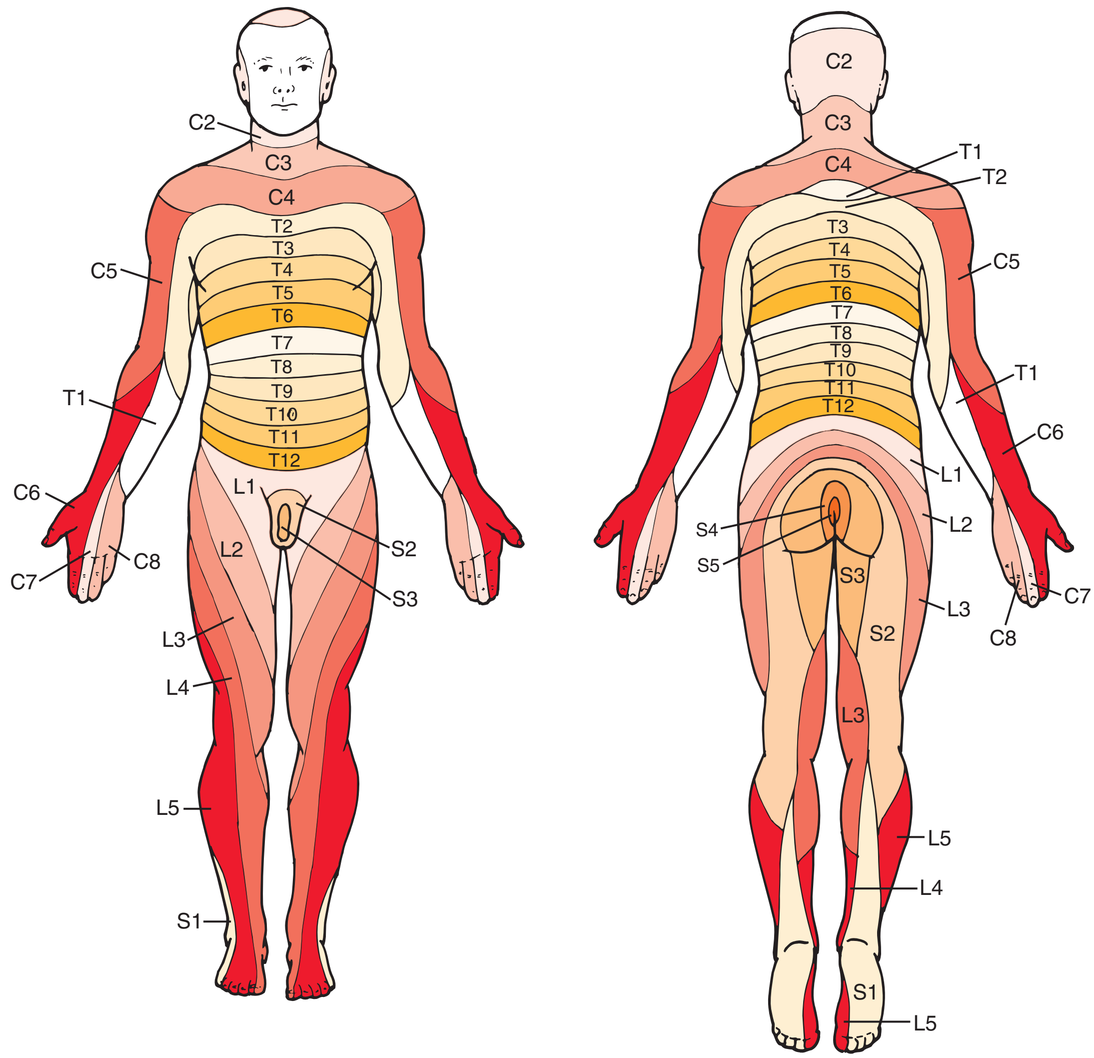

FIGURE 13.2 Dermatomes—anterior and posterior views.

BOX 13.2 Key Muscles for Testing Upper and Lower Quarter Myotomes[45]

Upper Quarter

C1–2	Cervical flexion
C3	Cervical side flexion
C4	Scapular elevation
C5	Shoulder abduction
C6	Elbow flexion and wrist extension
C7	Elbow extension and wrist flexion
C8	Thumb extension
T1	Finger abduction

Lower Quarter

L1–2	Hip flexion
L3	Knee extension
L4	Ankle dorsiflexion
L5	Big toe extension
S1	Ankle eversion and plantar flexion, hip extension
S2	Knee flexion
S3	No specific test action; intrinsic foot muscles (except abductor hallucis)

- **Complete or total injury of the plexus:** Complete paralysis from a total brachial plexus injury may occur as a complication of birth; it is known as Erb-Klumpke's paralysis and is associated with Horner's syndrome in one-third of those severely affected.[6]

Peripheral Nerves in the Upper Quarter

The brachial plexus terminates in five primary peripheral nerves that are responsible for innervating the tissues of the upper extremity: (1) musculocutaneous, (2) axillary, (3) median, (4) ulnar, and (5) radial nerves. Patterns of impairments from muscle weaknesses for each of these nerves are summarized in Table 13.1. Common sites for compression or tension injuries for each of the nerves are described in this section.

Axillary Nerve: C5, 6

The axillary nerve (Fig. 13.4) emerges from the posterior cord of the brachial plexus; it passes laterally through the axilla, sends a branch to the teres minor muscle, courses behind the surgical neck of the humerus, and innervates the deltoid muscle and overlying skin. The axillary nerve is vulnerable to

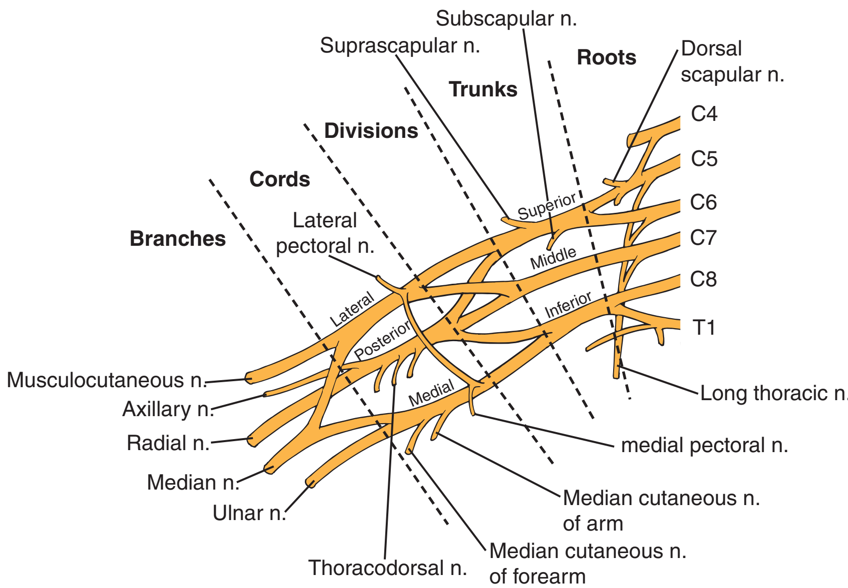

FIGURE 13.3 Brachial plexus.

TABLE 13.1 Patterns of Muscle Weakness and Functional Loss with Peripheral Nerve Injuries in the Upper Extremity

Nerve	Muscles Affected with Nerve Injury	Common Causes of Nerve Injury	Deformity	Primary Functional Loss
Axillary (C5, 6)	Deltoid	Dislocation of shoulder	"Square shoulder" from deltoid muscle atrophy	Weakness in shoulder abduction and lateral rotation; see shoulder shrugging and lateral bending of trunk to abduct/flex arm
	Teres minor	Fracture of surgical neck of humerus		
Musculo-cutaneous (C5–7)	Coracobrachialis Biceps brachii Brachialis	Projectile wounds	Atrophy (flatness) along flexor surface of upper arm	Weakness in elbow flexion especially with forearm supinated; may have slight subluxation of head of humerus
Median (C6–8, T1)	Forearm ▪ Pronator teres ▪ Palmaris longus ▪ Flexor digitorum profundus (radial portion) ▪ Flexor carpi radialis ▪ Flexor digitorum superficialis ▪ Flexor pollicis longus ▪ Pronator quadratus Wrist and hand ▪ Opponens pollicis ▪ Abductor pollicis brevis ▪ Flexor pollicis brevis (superficial head) ▪ Lumbricals I and II	Impingement in hypertrophied pronator teres Compression in carpal tunnel	Ape hand with atrophy in the thenar eminence	Absent forearm pronation, weak grip; no thumb abduction and opposition therefore unable to do tip-to-tip, tip-to-pad, and pad-to-pad prehension.

Continued

TABLE 13.1 Patterns of Muscle Weakness and Functional Loss with Peripheral Nerve Injuries in the Upper Extremity—cont'd

Nerve	Muscles Affected with Nerve Injury	Common Causes of Nerve Injury	Deformity	Primary Functional Loss
Ulnar (C8, T1)	Forearm	Cubital tunnel	Partial claw with atrophy between the metacarpals, with atrophy of hypothenar eminence and ulnar drifting of little finger	Use of 4th and 5th digits for spherical and cylindrical power grips, thumb for adduction, and finger abduction and adduction are lost
	■ Flexor carpi ulnaris ■ Flexor digitorum profundus (ulnar portion)	Impingement between heads of flexor carpi ulnaris		
	Wrist and hand ■ Abductor, opponens, and flexor digiti minimi ■ Lunbricals III and IV ■ Interossei ■ Adductor pollicis ■ Flexor pollicis brevis (deep head)	Compression in tunnel of Guyon at the wrist		
Radial (C5–8, T1)	Triceps brachii and anconeus Brachialis Brachioradialis Extensor carpi radialis longus and brevis and ulnaris Extensor digitorum communis and digiti quinti Supinator Abductor pollicis longus Extensor pollicis longus and brevis	Axilla Musculospiral groove Radial neck	Wrist drop	With high lesions affecting the triceps cannot push; weak supination; unable to make fist or grip objects unless wrist is stabilized in extension

injury with dislocation of the shoulder and fractures of the surgical neck of the humerus. If the upper trunk of the brachial plexus is stretched or injured, it affects the function of the axillary nerve. Shoulder abduction and lateral rotation are impaired when this nerve is affected.

Musculocutaneous Nerve: C5, 6

The musculocutaneous nerve (Fig. 13.4) emerges from the lateral cord of the brachial plexus and crosses the axilla with the median nerve; it pierces and innervates the coracobrachialis and then travels distally to innervate the biceps and brachialis muscles. It continues between these muscles to the flexor surface of the elbow; after emerging from the deep fascia at the elbow, it becomes the lateral cutaneous nerve of the forearm. Isolated impingement of this nerve is not common; injury to the lateral cord or the upper trunk of the brachial plexus affects the musculocutaneous nerve. When affected, the patient is unable to flex the elbow with the forearm supinated and may have some instability in the shoulder.

Median Nerve: C6–8

Bundles from the medial and lateral cords of the brachial plexus unite in the uppermost part of the arm to form the median nerve (Fig. 13.5). The median nerve courses the medial aspect of the humerus to the elbow, where it is deep in the cubital fossa under the bicipital aponeurosis, medial to the tendon of the biceps and brachial artery; it then moves into the forearm between the two heads of the pronator teres muscle. Hypertrophy of this muscle can compress the median nerve, producing symptoms that mimic carpal tunnel syndrome except that the forearm muscles (pronator teres, wrist flexors, extrinsic finger flexors) are involved in addition to the intrinsic muscles.

To enter the hand, the median nerve passes through the carpal tunnel at the wrist with the flexor tendons. The carpal

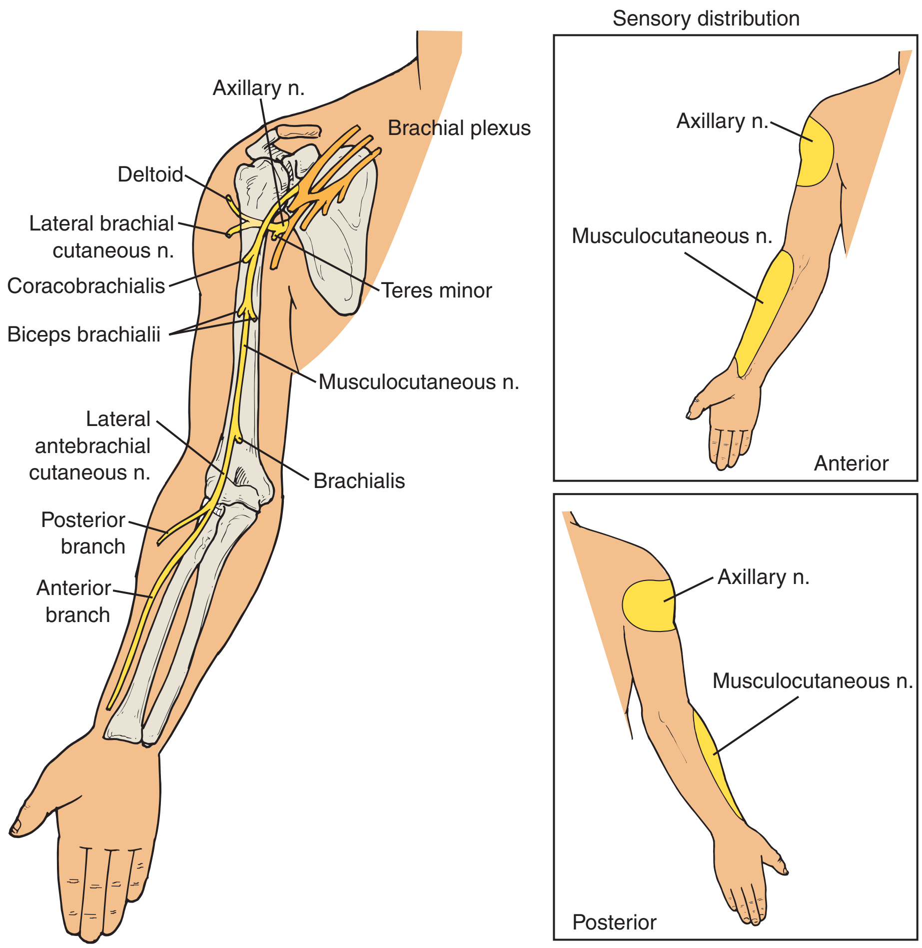

FIGURE 13.4 Sensory and motor innervations of the axillary (C5, 6) and musculocutaneous (C5, 6) nerves.

tunnel is covered by the thick, relatively inelastic transverse carpal ligament. Entrapment of the median nerve in the tunnel, called carpal tunnel syndrome, causes sensory changes and progressive weakness in the muscles innervated distal to the wrist resulting in ape hand deformity (thenar atrophy and thumb in the plane of the hand). Characteristics of this syndrome and management guidelines are described later in the chapter. The branch innervating the opponens muscle hooks over the carpal ligament two-thirds of the way up the thenar eminence and can be entrapped separately.[36]

Ulnar Nerve: C8, T1

The ulnar nerve (Fig. 13.6) emerges from the medial cord of the brachial plexus at the lower border of the pectoralis minor and descends the arm along the medial side of the humerus. It passes posterior to the elbow joint in the groove between the medial epicondyle of the humerus and the olecranon of the ulna. The groove is covered by a fibrous sheath, which forms the cubital tunnel. The nerve possesses considerable mobility to stretch around the elbow as it flexes, although the nerve can be easily irritated or entrapped at the elbow owing to its superficial location and anatomic arrangement.[65] It then passes between the humeral and ulnar heads of the flexor carpi ulnaris muscle, another site where impingement could occur.[65] The only extrinsic muscles innervated by the ulnar nerve are the flexor carpi ulnaris and ulnar half of the flexor digitorum profundus.

The ulnar nerve enters the hand through a trough formed by the pisiform bone and hook of the hamate bone and is covered by the volar carpal ligament and palmaris brevis muscle, forming the tunnel of Guyon. Trauma or entrapment in this region causes sensory changes and progressive weakness of muscles innervated distal to the site, resulting in partial claw-hand deformity. Injury to the nerve after it bifurcates leads to partial involvement, depending on the site of injury.[36,65] Characteristics of ulnar nerve impingement in the tunnel and management guidelines are described later in the chapter.

Radial Nerve: C6–8, T1

The radial nerve (Fig. 13.7) emerges directly from the posterior cord of the brachial plexus at the lower border of the pectoralis minor. As it descends the arm, it winds around the posterior aspect of the humerus in the musculospiral groove and continues to the radial aspect of the elbow. In the arm it innervates the triceps, anconeus, and upper portion of the extensor and supinator group of the forearm. Injury to this nerve may occur with shoulder dislocations and midhumeral

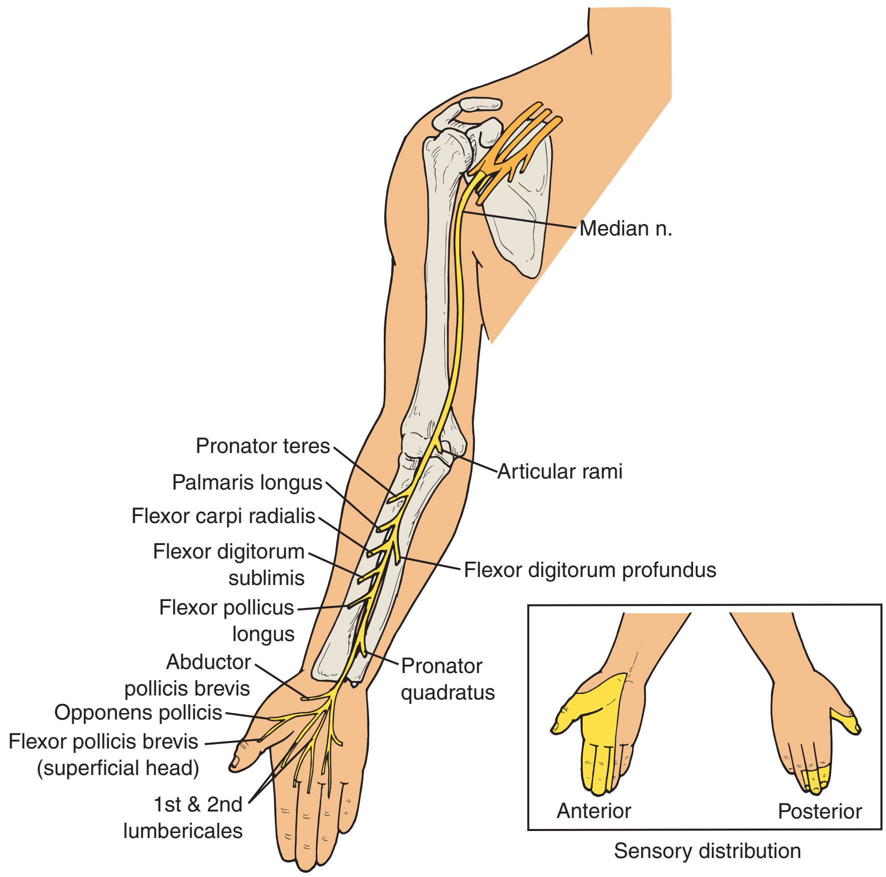

FIGURE 13.5 Sensory and motor innervations of the median nerve (C6–8, T1).

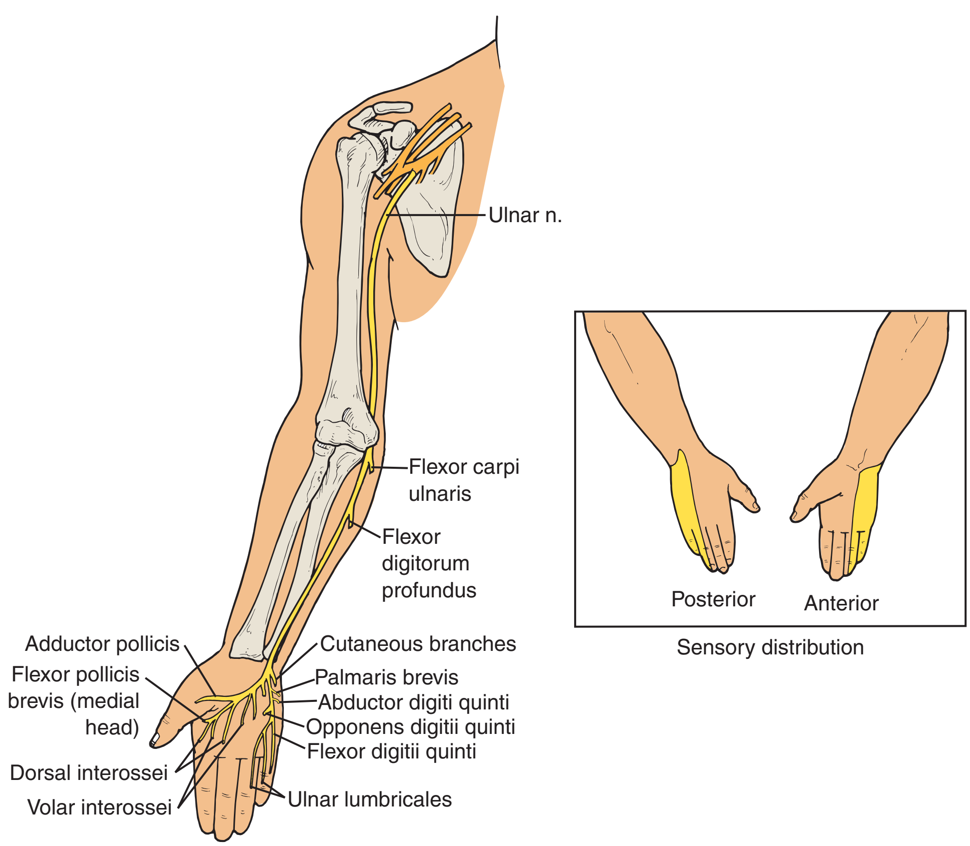

FIGURE 13.6 Sensory and motor innervations of the ulnar nerve (C8, T1).

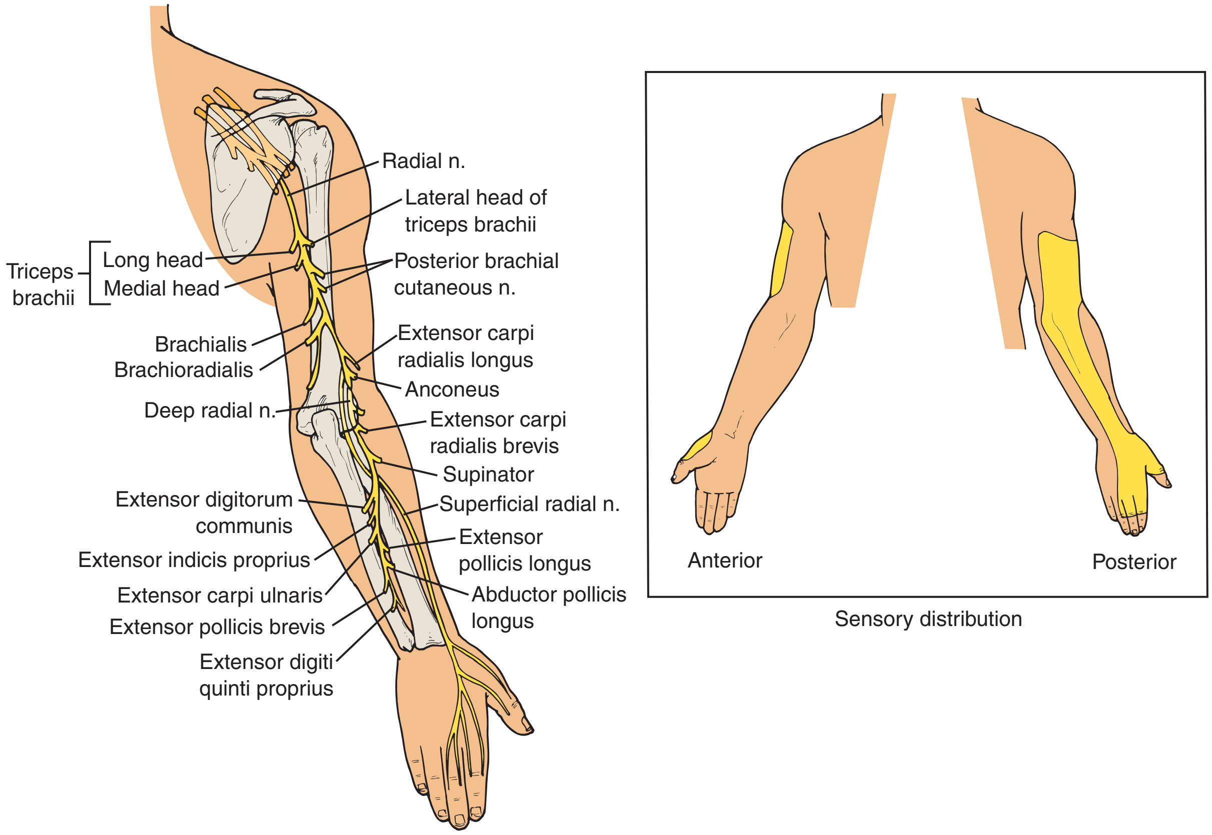

FIGURE 13.7 Sensory and motor innervations of the radial nerve (C6–8, T1).

fractures. Also known to all therapists is "crutch palsy," a condition of nerve compression caused by leaning on axillary crutches. "Saturday night palsy" occurs when sleeping with the person's head on the arm that is slung over the back of a chair or open car window. The triceps is involved only if the compression or injury to the nerve occurs close to the axilla. At the elbow, the radial nerve pierces the lateral muscular septum anterior to the lateral epicondyle and passes under the origin of the extensor carpi radialis brevis; it then divides into a superficial and a deep branch. The deep branch may become entrapped as it passes under the edge of the extensor carpi radialis brevis and the fibrous slit in the supinator, causing progressive weakness in the wrist and finger extensor and supinator muscles (except the extensor carpi radialis longus, which is innervated proximal to the bifurcation). Impingement may occur here and may be erroneously called tennis elbow (lateral epicondylitis—see Chapter 18). The deep branch passes around the neck of the radius and may be injured with a radial head fracture. The superficial radial nerve may undergo direct trauma that causes sensory changes in the distribution of the nerve.

The radial nerve enters the hand on the dorsal surface as the superficial radial nerve, which is sensory only; therefore, injury to it in the wrist or hand does not cause any motor weakness. The influence of the radial nerve on hand musculature is entirely proximal to the wrist. Injury proximal to the elbow results in wrist drop and inability to actively extend the wrist and fingers. This affects the length-tension relationship of the extrinsic finger flexors, resulting in an ineffective grip unless the wrist is splinted in partial extension. Injury of the midforearm affects only the supinator muscle and extrinsic abductor and extensor pollicis muscles.

Lumbosacral Plexus

The lumbar plexus is formed by the anterior primary divisions of the nerve roots L1, L2, L3, and part of L4 (Fig. 13.8 A); the sacral plexus is formed from L4, L5, S1, and parts of S2 and S3 (Fig. 13.8 B). As with the brachial plexus, the branches and divisions of the LS plexus organize the content of each of the peripheral nerves coursing into the lower extremity. In addition, the anterior primary rami of the plexus receive postganglionic sympathetic fibers from the sympathetic chain that innervate blood vessels, sweat glands, and piloerector muscles in the lower extremity. Isolated injuries to the lumbar plexus or sacral plexus are not common; symptoms more commonly arise from disc lesions or spondylitic deformities that affect one or more nerve roots or from tension or compression of specific peripheral nerves.

Peripheral Nerves in the Lower Quarter

The lumbosacral plexus terminates in three primary peripheral nerves, which are responsible for innervating the tissues of the lower extremity. They are the femoral and obturator

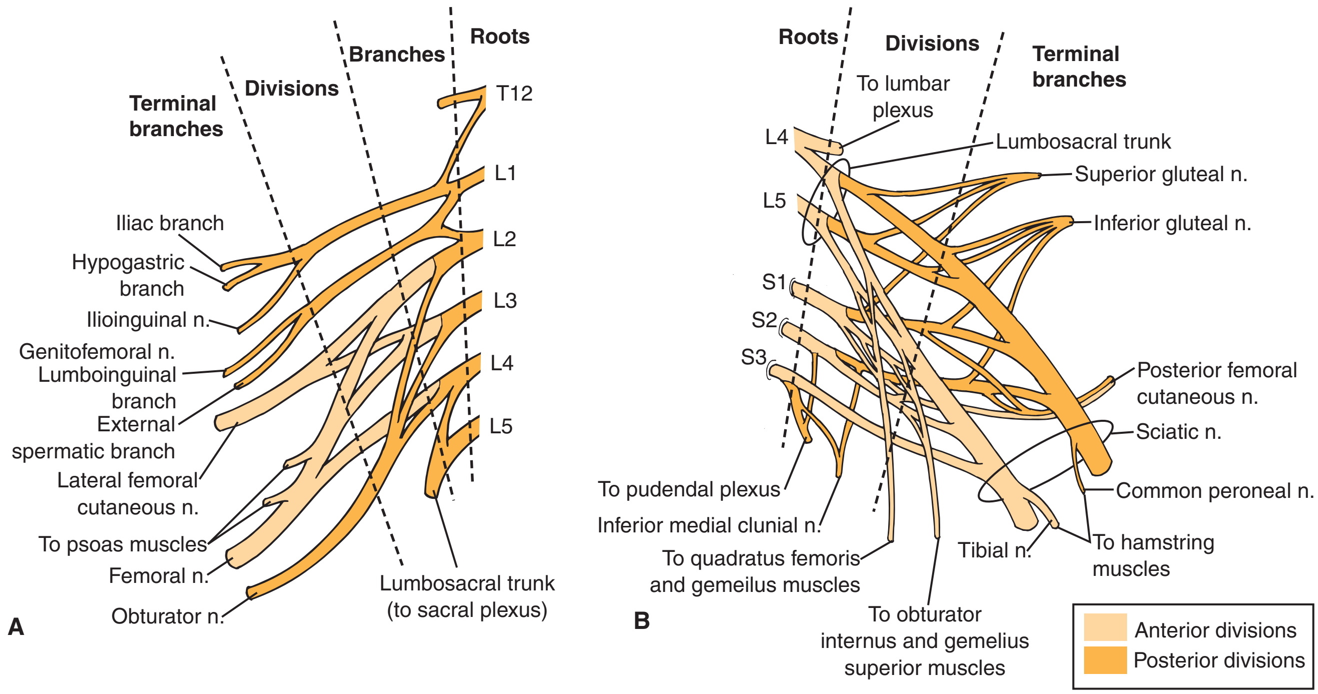

FIGURE 13.8 (A) Lumbar plexus and **(B)** sacral plexus.

nerves from the lumbar plexus and the sciatic nerve from the sacral plexus. Patterns of impairments from muscle weakness for each of these nerves are summarized in Table 13.2. Common sites for compression or tension injuries are described in this section.

Femoral Nerve: L2–4

The femoral nerve (Fig. 13.9) arises from the three posterior divisions of the lumbar plexus. It emerges from the lateral border of the psoas muscle superior to the inguinal ligament and descends underneath the ligament to the femoral triangle, lateral to the femoral artery, to innervate the sartorius and quadriceps muscle group. The iliopsoas is supplied superior to the ligament. Injuries to the nerve may occur with trauma, such as fractures of the upper femur or pelvis, during reduction of congenital dislocation of the hip, or from pressure during a forceps labor and delivery—resulting in weakness of hip flexion and loss of knee extension. Symptoms may occur from neuritis in diabetes mellitus.

Obturator Nerve: L2–4

The obturator nerve (Fig. 13.9) arises from the three anterior divisions of the lumbar plexus. It descends through the obturator canal in the medial obturator foramen to the medial side of the thigh to innervate the adductor muscle group and obturator externus. Isolated injury to this nerve is rare, although uterine pressure and damage during labor may cause the injury. If damaged, adduction and external rotation of the thigh are impaired, with the individual having difficulty crossing his or her legs.

Sciatic Nerve: L4, 5; S1–3

The sciatic nerve (Fig. 13.10) emerges from the sacral plexus as the largest nerve in the body; its component parts—the tibial and common peroneal nerves—can be differentiated in the common sheath. Muscles in the buttock region (external rotators and gluteal muscles) are innervated by small nerves from the sacral plexus, which emerge proximal to formation of the sciatic nerve. The sciatic nerve exits the pelvis through the greater sciatic foramen and typically courses below, although sometimes through, the piriformis muscle. Piriformis syndrome may occur from a shortened muscle, causing compression and irritation of the nerve at this site. The nerve is protected under the gluteus maximus as it courses between the ischial tuberosity and greater trochanter, although injury may occur in this region with hip dislocation or reduction. The tibial portion of the sciatic nerve innervates the biarticular hamstring muscles and a portion of the adductor magnus; the common peroneal portion innervates the short head of the biceps femoris. Proximal to the popliteal fossa, the sciatic nerve terminates when the tibial and common peroneal nerves emerge as separate structures.

Tibial/Posterior Tibial Nerve: L4, 5; S1–3

The tibial nerve (Fig. 13.10) forms from the anterior primary rami of the sacral plexus, courses with the common peroneal nerve as the sciatic nerve, and then emerges as a separate nerve proximal to the popliteal fossa. After coursing through the popliteal fossa, it sends a branch that joins a branch from the common peroneal nerve to form the sural nerve and continues on as the posterior tibial nerve. In the leg, it innervates the

TABLE 13.2 Patterns of Muscle Weakness and Functional Loss with Peripheral Nerve Injuries in the Lower Extremity

Nerve	Muscles Affected with Nerve Injury	Common Sites of Nerve Compression/Tension or Causes of Nerve Injury	Deformity/Symptoms	Primary Functional Loss
Femoral (L2–4)	Iliacus Sartorius Pectineus Quadriceps group	Pelvic or upper femur fractures, during reduction of congenital dislocation of the hip, or from pressure during a forceps labor and delivery	Atrophy in anterior thigh	Weakness or inability to flex thigh and extend knee. Gait and weight-bearing disturbances: unable to control knee flexion during loading response or hip flexion to initiate swing
Obturator (L2–4)	Obturator externus Adductor muscle group	Similar to femoral nerve. Pressure from gravid uterus and difficult labor	Atrophy medial thigh	Difficulty crossing the legs. Impaired adduction and rotation of thigh
Sciatic:divides into tibial and common peroneal nerves	Hamstring group Adductor magnus	Compression from tight piriformis muscle; hip dislocation; fracture of the femur	"Sciatica"—pain radiating in posterior thigh and leg; atrophy posterior thigh, leg, and foot	Weak knee flexion and loss of ankle and foot control affecting all phases of gait
Tibial (L4–S3): divides into medial and lateral plantar nerves	Plantar flexors Popliteus Tibialis posterior, flexor digitorum longus and flexor hallucis longus		Atrophy in calf	Inability to plantar flex ankle or flex the toes. Gait impairment in terminal stance
■ Medial and lateral plantar nerves	Abductor hallucis, flexor hallucis brevis, lumbricals, interossei, and quadratus plantae	Compromise in tarsal tunnel; irritation from pes planus or pes cavus	Foot deformities such as pes cavas and claw toes; foot strain, painful heel	
Common peroneal (L4–S2): divides into deep and superficial peroneal nerves		Compression from crossing legs; injury from fracture at head/neck of fibula		Gait impairment during the loading response with foot slap and during swing phase with excessive hip flexion (steppage gait) to clear the toes
■ Deep peroneal nerve	Ankle dorsiflexors, toe extensors, peroneus tertius		Foot drop; may develop pes valgus	
■ Superficial peroneal nerve	Peroneus longus and brevis		May develop equinovarus	

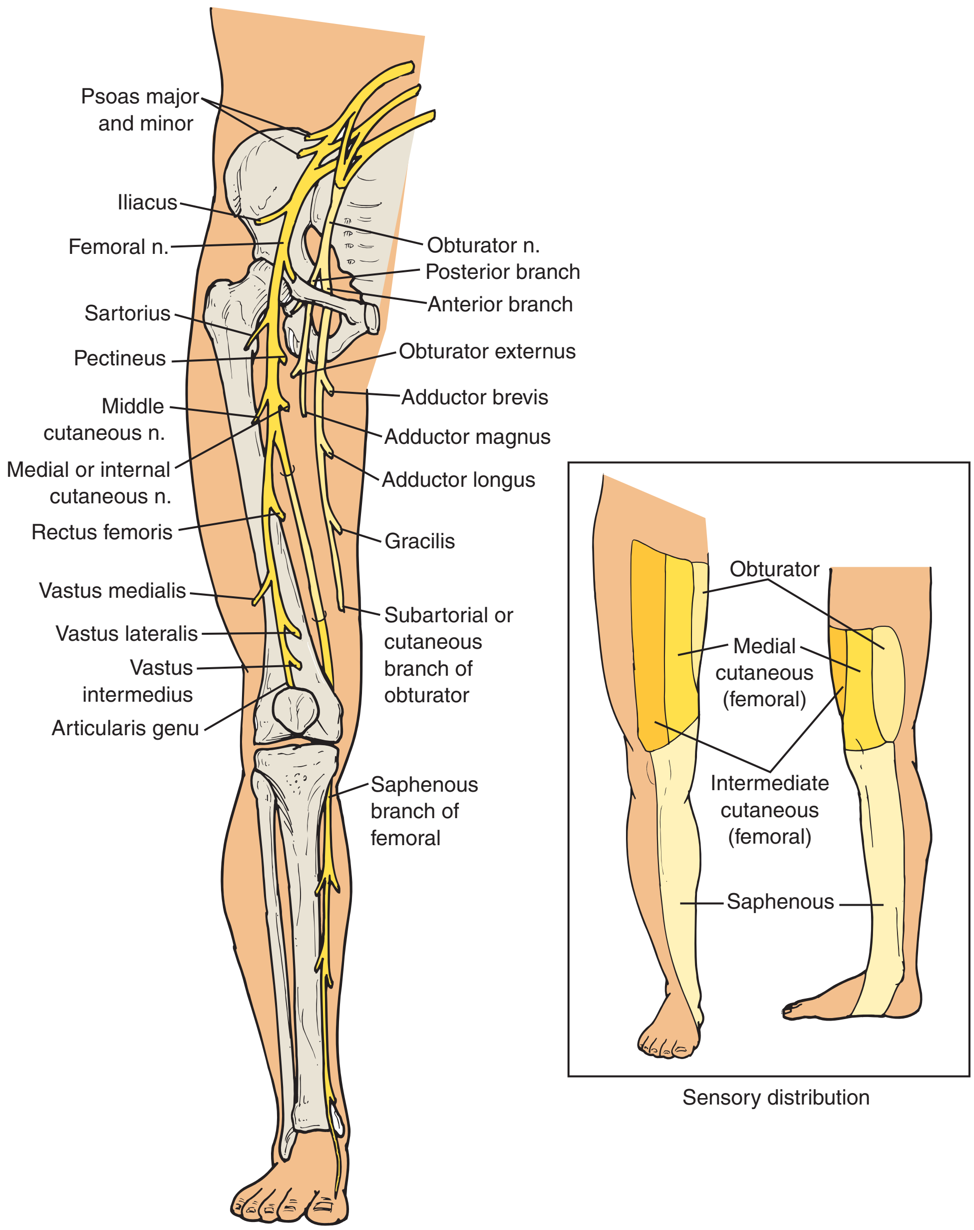

FIGURE 13.9 Sensory and motor innervations of the femoral (L2–4) and obturator (L2–4) nerves.

muscles of the posterior compartment, including the plantar flexors, popliteus, tibialis posterior, and extrinsic toe flexors.

In its approach to the foot, the nerve occupies a groove behind the medial malleolus along with the tendons of the tibialis posterior, flexor hallucis longus, and flexor digitorum longus; the groove is covered by a ligament, forming a tunnel. Entrapment, usually from a space-occupying lesion, is known as *tarsal tunnel syndrome*. The nerve then divides into the medial and lateral plantar and calcaneal nerves.

Plantar and calcaneal nerves. The plantar and calcaneal nerves may become entrapped as they turn under the medial aspect of the foot and pass through openings in the abductor hallucis muscle, especially with overpronation of the foot, which stresses the nerves against the fibrous-edged openings in the muscle.[36] Symptoms elicited are similar to acute foot strain (tenderness at the posteromedial plantar aspect of the foot), painful heel (inflamed calcaneal nerve), and pain in a pes cavus foot.[36] The medial and lateral plantar nerves innervate all the intrinsic muscles of the foot except the extensor digitorum brevis. The innervation pattern of the lateral plantar nerve in the foot corresponds to the ulnar nerve in the hand, and the medial plantar nerve corresponds to the median nerve. Weakness and postural changes in the foot, such as pes cavus and clawing of the toes, may occur with nerve compression or injury.

Common Peroneal Nerve: L4, 5; S1, 2

After it bifurcates from the sciatic nerve in the knee region, the common peroneal nerve (Fig. 13.11) passes between the biceps femoris tendon and lateral head of the gastrocnemius muscle,

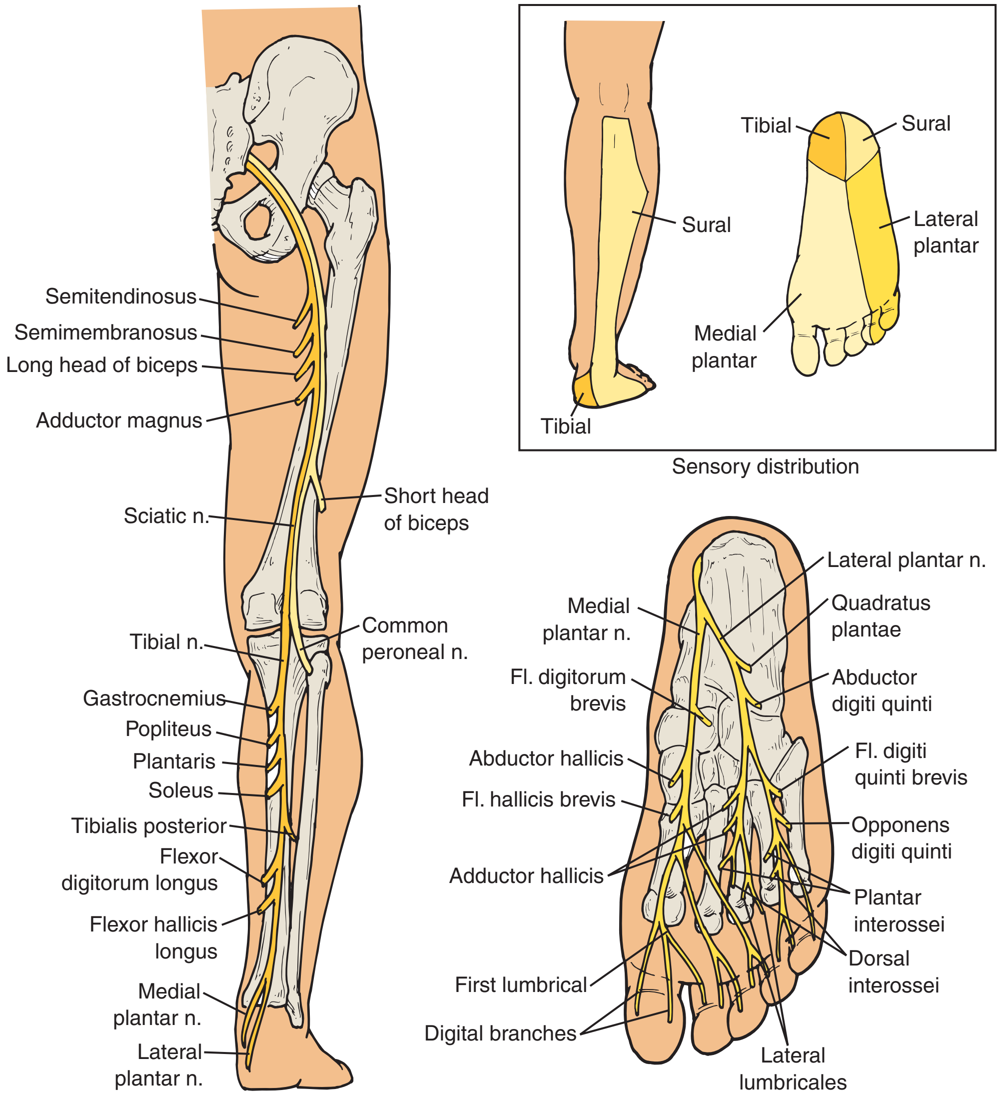

FIGURE 13.10 Sensory and motor innervations of the sciatic nerve (L4, 5,S1–3) and tibial nerve (L4, 5, S1–3).

sends a branch to join the tibial nerve and form the sural nerve, and then comes laterally around the fibular neck and passes through an opening in the peroneus longus muscle. Pressure or force against the nerve in this region can cause neuropathy, including sensory changes and weakness in the muscles of the anterior and lateral compartments of the leg. Injury also occurs subsequent to fracture of the head of the fibula, from rupture of the lateral collateral ligament of the knee, or from a tightly applied cast. Also, most people have experienced their foot "falling asleep" from sustained pressure when crossing their legs. The common peroneal nerve bifurcates just below the neck of the fibula into the superficial and deep peroneal nerves.

Superficial peroneal nerve. The superficial peroneal nerve descends along the anterior part of the fibula, innervating the peroneus longus and brevis muscles and continues on with cutaneous innervations. Injury to just this nerve primarily affects eversion. Over time, equinovarus may develop from unopposed inversion.

Deep peroneal nerve. The deep peroneal nerve descends the leg along the interosseous membrane and distal tibia, innervating the ankle dorsiflexors, toe extensors, and peroneus tertius. In the foot, it innervates the extensor digitorum brevis. Injury to the deep peroneal nerve results in foot drop and unopposed eversion during gait. Over time, pes valgus may develop.

Impaired Nerve Function

Nerve Injury and Recovery

Peripheral nerve injury may result in motor, sensory, and/or sympathetic impairments. In addition, pain may be a symptom of nerve tension or compression, because the connective tissue and vascular structures surrounding and in the

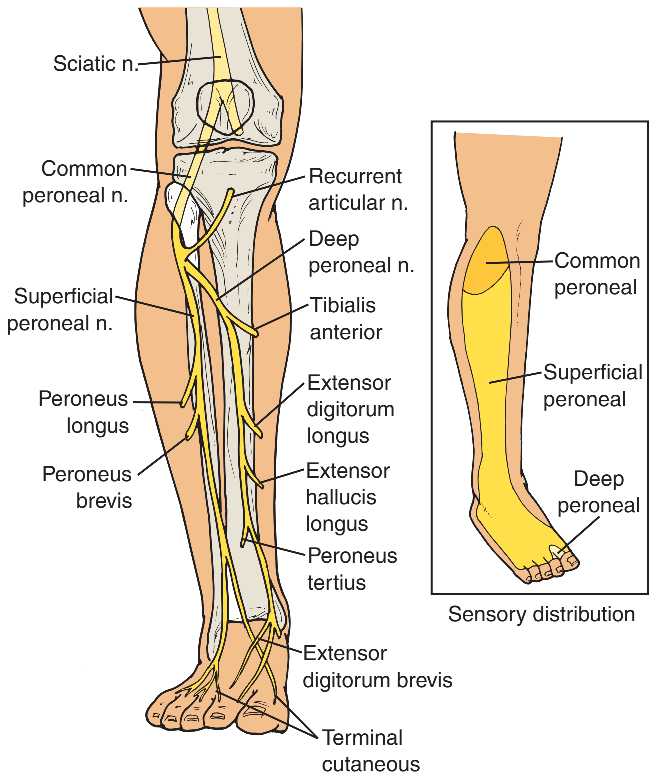

FIGURE 13.11 Sensory and motor innervations of the peroneal nerve (L4, 5, S1, 2).

peripheral nerves are innervated, and the peripheral nerve function is sensitive to hypoxic states. Knowing the mechanism of injury and the clinical signs and symptoms helps the clinician determine the potential outcome for the patient and develop a plan of care.[62]

Mechanisms of Nerve Injury

Nerves are mobile and capable of considerable torsion and lengthening owing to their arrangement. Yet, they are susceptible to various types of injury including[9,62]:

- Compression (sustained pressure applied externally, such as tourniquet, or internally, such as from bone, tumor, or soft tissue impingement resulting in mechanical or ischemic injury).
- Laceration (knife, gunshot, surgical complication, injection injury).
- Stretch (excessive tension, tearing from traction forces).
- Radiation.
- Electricity (lightening strike, electrical malfunction).

Injury may be complete or partial and produces symptoms based on the location of the insult.

Biomechanical injuries to the peripheral nervous system are most commonly the result of friction, compression, and stretch.[9,10] Secondary injury can be from blood or edema. Compressive forces can affect the microcirculation of the nerve, causing venous congestion and reduction of axoplasmic transport,[47] thus blocking nerve impulses; if sustained, the compression can cause nerve damage. The endoneurium helps maintain fluid pressure and may provide cushioning for nerves, especially when the nerves are close to the surface and subject to greater pressure.

The insult can be acute from trauma or chronic from repetitive trauma or entrapment. Sites where a peripheral nerve is more vulnerable to compression, friction, or tension include tunnels (soft tissue, boney, fibro-osseus), branches of the nervous system (especially if the nerve has an abrupt angle), points at which a nerve is relatively fixed when passing close to rigid structures (across a boney prominence), and at specific tension points.

Response to injury can be pathophysiological or pathomechanical, leading to symptoms derived from adverse tension on the nervous system. Results may be intraneural and/or extraneural.[10]

- ***Intraneural.*** Pathology that affects the conducting tissues (e.g., hypoxia or demyelination) or connective tissues of the nerve (e.g., scarring of epineurium or irritation of dura mater) may restrict the elasticity of the nervous system itself.
- ***Extraneural.*** Pathology that affects the nerve bed (e.g., blood), adhesions of epineurium to another tissue (e.g., a ligament), and swelling of tissue adjacent to a nerve (e.g., foraminal stenosis) may restrict the gross movement of the nervous system in relation to surrounding tissues.

Classification of Nerve Injuries

Nerve injuries are classified using either the Seddon or Sunderland classification systems; both are based on structural and functional changes that occur in the nerve with various degrees of damage.[9,62,63,65] These systems describe the degree of injury to nerve substructures and the effect on prognosis. Seddon's system describes three levels of pathology: neuropraxia, axonotmesis, and neurotmesis. Sunderland's classification details five levels of injury and potential for recovery. The characteristics of Seddon's classification of nerve injuries are summarized in Box 13.3 and are compared with Sunderland's classification in Figure 13.12.

Recovery from Nerve Injuries

Nerve tissue that has become irritated from tension, compression, or hypoxia may not have permanent damage and shows signs of recovery when the irritating factors are eliminated.[11] When the nerve has been injured, recovery is dependent on several factors including the extent of injury to the axon and its surrounding connective tissue sheath, the nature and level of the injury, the timing and technique of the repair (if necessary), and the age and motivation of the person.[9,22,25,61,71]

- ***Nature and level of injury.*** The more damage to the nerve and tissues, the more tissue reaction and scarring occur. Also, the proximal aspect of a nerve has greater combinations of motor, sensory, and sympathetic fibers,

BOX 13.3 Seddon's Classification and Characteristics of Nerve Injury[62,63,65]

Neuropraxia

- Segmental demyelination
- Action potential slowed or blocked at point of demyelination; normal above and below point of compression
- Muscle does not atrophy; temporary sensory symptoms
- The result of mild ischemia from nerve compression or traction
- Recovery is usually complete

Axonotmesis

- Loss of axonal continuity but connective tissue coverings remain intact
- Wallerian degeneration distal to lesion
- Muscle fiber atrophy and sensory loss
- The result of prolonged compression or stretch causing infarction and necrosis
- Recovery is incomplete—surgical intervention may be required

Neurotmesis

- Complete severance of nerve fiber with disruption of connective tissue coverings
- Wallerian degeneration distal to lesion
- Muscle fiber atrophy and sensory loss
- The result of gunshot or stab wounds, avulsion, rupture
- No recovery without surgery—recovery depends on surgical intervention and correct regrowth of individual nerve fibers in endoneural tubes

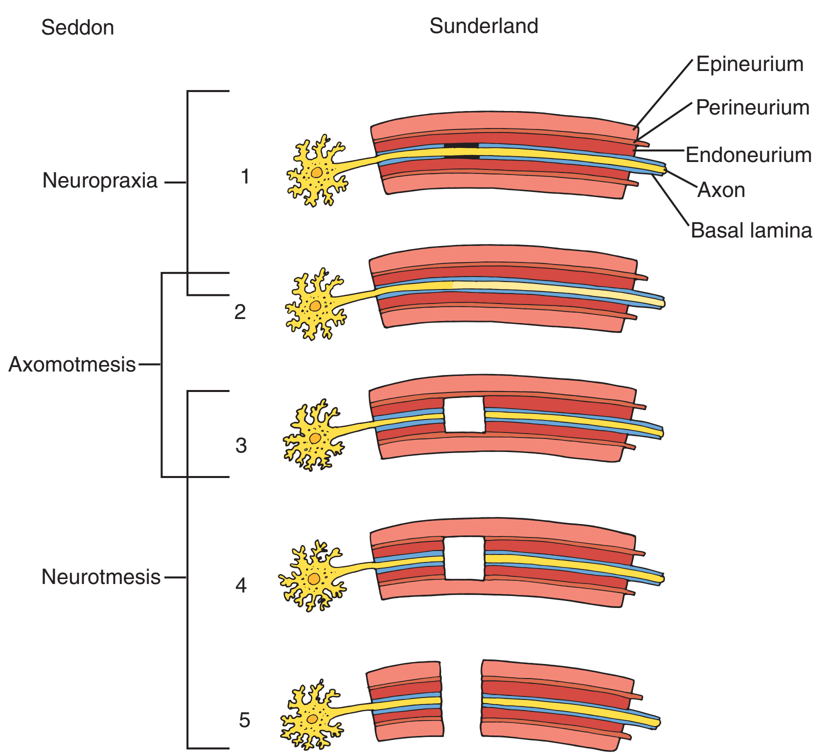

FIGURE 13.12 Comparison of Sunderland's and Seddon's classifications of nerve injuries. **(1)** First degree injury (neuropraxia): minimal structural disruption—complete recovery; **(2)** second degree (axonotmesis): complete axonal disruption with wallerian degeneration—usually complete recovery; **(3)** third degree (may be either axonotmesis or neurotmesis): disruption of axon and endoneurium—poor prognosis without surgery; **(4)** fourth degree (neurotmesis): disruption of axon, endoneurium, and perineurium—poor prognosis without surgery; **(5)** fifth degree (neurotmesis): complete structural disruption—poor prognosis without microsurgery.[62,65]

so disruption there results in a greater chance of mismatching the fibers, thus affecting regeneration. Regeneration is often said to occur at a rate of 1 inch per day,[22] but rates from 0.5 to 9.0 mm per day have been reported based on the nature and severity of the injury, duration of denervation, condition of the tissues, and whether surgery is required.[9]

- ***Timing and technique of repair.*** Laceration or crush injuries that disrupt the integrity of the entire nerve require surgical repair. For optimal nerve regeneration, timing of the repair is critical, as are the skill of the surgeon and the technique used to align the segments accurately and avoid tension at the suture line. Different regenerative potential outcomes following nerve repair have also been reported based on groupings of specific nerves.[57]
  - Excellent regenerative potential: radial, musculocutaneous, and femoral nerves
  - Moderate regenerative potential: median, ulnar, and tibial nerves
  - Poor regenerative potential: peroneal nerve
- ***Age and motivation of the patient.*** The nervous system must adapt and relearn use of the pathways once regeneration occurs. Motivation and age play a role in this, especially in the very young and the elderly.[57]

Outcomes of Nerve Regeneration

Smith[62] described five possible outcomes of nerve regeneration.

1. Exact reinnervation of its native target organ with return of function
2. Exact reinnervation of its native target organ but no return of function due to degeneration of the end organ
3. Wrong receptor reinnervated in the proper territory; therefore, improper input
4. Receptor reinnervation in wrong territory causing false localization of input
5. No connection with an end organ

Management Guidelines: Recovery from Nerve Injury

In general, recovery from nerve injury can be viewed as occurring in three phases.

- ***Acute phase.*** This is early after injury or surgery when the emphasis is on healing and prevention of complications.
- ***Recovery phase.*** This is when reinnervation occurs. Emphasis is on retraining and re-education.
- ***Chronic phase.*** This occurs when the potential for reinnervation has peaked, and there are significant residual deficits. The emphasis is training compensatory function.

Effective management must consider not only nerve healing but connective tissue healing in general (see Chapter 10).[18] Management guidelines for the three phases of recovery from peripheral nerve injury are summarized in Box 13.4.

Acute Phase

Following injury or immediately after surgery (e.g., following decompression and release or following repair of a lacerated nerve), there may be a brief period of immobilization to protect the nerve, minimize inflammation, and minimize tension at the injured/repaired site. As soon as allowed, begin:

- ***Movement.*** Begin range of motion (ROM) to minimize joint and connective contractures and adhesions. This is dictated by the surgeon and type of surgery.
- ***Splinting or bracing.*** Splinting or bracing may be necessary to prevent deformities due to strength imbalances (e.g., use of a radial nerve splint to prevent wrist drop; a median nerve splint to position the thumb in opposition; a plantarflexion splint to prevent foot drop) and to prevent undue stress on the healing nerve tissue.
- ***Patient education.*** Teach the patient safe movements and ways to protect the extremity to avoid injury due to loss of sensation.

BOX 13.4 MANAGEMENT GUIDELINES—
Recovery from Peripheral Nerve Injury

***Acute phase*: immediately after injury or surgery**
- *Immobilization*: time dictated by surgeon
- *Movement*: amount and intensity dictated by type of injury and surgical repair
- *Splinting or bracing*: may be necessary to prevent deformities
- *Patient education*: protection of the part (see Box 13.5)

***Recovery phase*: signs of reinnervation (muscle contraction, increased sensitivity)**
- *Motor retraining*: muscle "hold" in the shortened position
- *Desensitization*: multiple textures for sensory stimulation; vibration
- *Discriminative sensory reeducation*: identification of objects with, then without, visual cues

***Chronic phase*: reinnervation potential peaked with minimal or no signs of neurological recovery**
- *Compensatory function*: compensatory function is minimized during the recovery phase but is emphasized when full neurological recovery does not occur
- *Preventive care*: emphasis on lifelong care to involved region (see Box 13.5)

Recovery Phase

The recovery phase begins with signs of reinnervation (volitional muscle contraction and hypersensitivity). With nerve regeneration and recovery, begin:

- ***Motor retraining.*** When signs of volutional muscle contraction occur, position the muscle in its shortened position; then ask the patient to hold. Provide assistance as needed to prevent the part from "falling" out of the shortened position.
  - Use electrical stimulation to reinforce this active effort.
  - When the muscles demonstrate control of some range, begin gravity-eliminated, active-assistive ROM. Continue to protect the weak muscles with a splint or brace.
- ***Desensitization.*** As nerves regenerate, the person experiences increased sensitivity (hypersensitivity) in the area that had previously been without sensation. Use a graded series of modalities and procedures to decrease the irritability and increase sensory awareness.[61] Suggestions are described in Box 13.5.
- ***Discriminative sensory re-education.*** This is the process of retraining the brain to recognize a stimulus once the hypersensitivity diminishes. Techniques are summarized in Box 13.5.
- ***Patient education.*** Instruct the patient to resume use of the extremity gradually while monitoring pain, swelling, or any discoloration; if necessary, modify or temporarily avoid any aggravating activities. While the nerve is recovering or if nerve recovery is incomplete, teach the patient preventive care to avoid injury (see Box 13.6).

Chronic Phase

When the potential for reinnervation has peaked and there are minimal or no signs of reinnervation, emphasize training for compensatory function. The person will probably have to continue to wear the supportive splint or brace, and preventive care must continue indefinitely.

BOX 13.5 Desensitization and Sensory Re-education Techniques

Suggestions for graded modalities and procedures for desensitizing:

- Use multiple types of textures or contact for sensory stimulation, such as cotton, rough material, sandpaper of various grades, and Velcro. The textures can be wrapped around dowel rods for finger manipulation or to stroke along the skin.
- Place contact particles, such as cotton balls, beans, macaroni, sand, or other material, with various degrees of roughness in tubs or cans, so the patient can run the involved hand or foot through the material. Have the patient begin by manipulating or placing the extremity in the least irritating texture for 10 minutes. As tolerance improves, progress to the next texture of slightly more irritating but tolerable stimulus. Maximum progress occurs when the most irritating texture is tolerated.
- Use vibration. Pattern of recovery after nerve injury is pain (hypersensitivity), perception of slow vibration (30 cps), moving touch, constant touch, rapid vibration (256 cps), and awareness from proximal to distal.[62]

Suggestions for retraining the brain to recognize a stimulus:

- Begin by using a moving touch stimulus, such as the eraser end of a pencil, and stroke over the area. The patient first watches, then closes his or her eyes, and tries to identify *where* touch occurred.
- Progress from stroking to using constant touch.
- When the patient is able to localize constant touch, progress to identification of familiar objects of various sizes, shapes, and textures.
- For the hand, use familiar household and personal care objects, such as keys, eating utensils, blocks, toothbrush, and safety pins.
- For the feet, have the patient walk on various surfaces, such as grass, sand, wood, pebbles, and uneven surfaces.

BOX 13.6 Patient Instructions for Preventive Care After Nerve Injury

While the nerve is regenerating, or if nerve recovery is incomplete:

- Inspect skin regularly; provide prompt treatment of wounds or blisters.
- Compensate for dryness with massage creams or oils.

In the upper extremity:

- Avoid handling hot, cold, sharp, or abrasive objects.
- Avoid sustained grasps; change use of tools frequently.
- Redistribute hand pressure by building up the size of the handles.
- Wear protective gloves.

In the lower extremity:

- Wear protective shoes that fit properly.
- Inspect feet regularly for pressure points (reddened area) and modify shoes or provide protection if they occur.
- Do not walk barefoot, especially in the dark or on rough surfaces.
- Shift weight frequently when standing for long periods.

Neural Tension Disorders

Normally, the nervous system has considerable mobility to adapt to the wide range of movements imposed on it by daily activities. Still, there are sites where nerves are vulnerable to increased pressure or tension, especially when excessive or repetitive stresses or strains are imposed on the tissues surrounding the nerves or on the nerves themselves. If a nerve is compressed as it passes near a boney structure or through a confined space, undue tension may be placed on it as movement occurs proximal or distal to that site. This may be magnified if there is adhesive scar tissue or swelling that restricts

mobility. When examining a patient, the therapist needs to be alert to symptoms described by the patient and able to understand and interpret positive signs detected with testing maneuvers.

This section summarizes the tests of provocation and describes the techniques that have been reported to mobilize components of the nervous system in order to improve the patient's outcome.[10]

Symptoms and Signs of Impaired Nerve Mobility

History

Vascular and mechanical factors can lead to nerve pathology. Pain is the most common symptom. Sensory responses, reported as stretch pain or paresthesia, occur when tissues are in the neural stretch position.[14] Clinical reasoning is used to understand the possible mechanism of injury, such as pathological insult to the nervous tissue or surrounding tissues or symptoms from movement patterns that place tension on the neural tissues and reproduce symptoms.

Tests of Provocation

Neurodynamic test maneuvers are performed to detect tension signs in the neural tissue. The upper limb tension test (ULTT), upper limb neurodynamic test (ULNT), straight leg raise (SLR), and slump test are familiar terms that describe various tests and procedures. The reader is referred to textbooks by Butler for greater details and variations of these tests.[10,11] Points regarding the tests:

- Because the test positions place stress across multiple joints, every joint in the chain must be tested separately for range, mobility, and symptom provocation prior to nerve tension testing so any restriction that occurs during the test is not the result of joint or periarticular tissue limitations. Coppieters and associates[14] demonstrated that the stretch position altered the available ROM and sensory responses in 35 normal male subjects during neurodynamic testing and reiterated the importance of looking at other influences prior to neural-tension testing.
- Additional tests include nerve palpation, sensation testing, reflex testing, and muscle testing.[46]
- The test positions and maneuvers used to detect nerve tension and mobility are the same as the treatment positions and maneuvers.
- Tension signs are stretch pain or paresthesias that occur when the neurological system is stretched across multiple joints and is relieved when one of the joints in the chain is moved out of the stretch position.

General testing procedure: Carefully elongate the nerve across each joint in succession until there is symptom provocation (this is described in detail in the techniques section). When symptoms occur, note the final position. It is important to recognize that in highly irritable or restrictive conditions full range is not possible. Once symptoms are provoked, move one of the joints in the chain out of the stretch position to see if the symptoms are relieved. Repeat with each of the joints in the chain until the mobility pattern of the nerve is understood.

Causes of Symptoms

Butler[10] proposed that symptoms are the result of tension being placed on some component of the nervous system. If compression is preventing normal mobility, tension signs occur when the nerve is stressed either proximal or distal to the site of compression. Restriction of movement can be from inflammation and scarring between the nerve and the tissue through which it runs or from actual changes in the nerve itself.[10]

NOTE: Cadavaric and in vivo ultrasound imaging studies have demonstrated that movement and tension placed on upper quadrant nerve tissue occur to various degrees with neck, shoulder girdle, and upper extremity postures and movements[13a,21,31,34]; and movement and tension placed on the sciatic, tibial, and plantar nerves occur to various degrees with hip, knee, ankle, and toe movements.[1,8,13] However, DiFabio[20] cautioned that there is lack of evidence that neural tension tests are "sensitive and specific indicators of impairments caused by abnormal neural mobility" or that neural tissue can be mobilized independently of other structures. As with many manual testing techniques, the sensitivity and validity of the tests have yet to be determined. The efficacy of interventions based on these maneuvers has been presented in the literature,[33] although evidence is lacking to support or refute this approach to intervention with patients who demonstrate positive signs.

FOCUS ON EVIDENCE

A recent systematic review of research on therapeutic efficacy of neural mobilization evaluated 10 randomized controlled studies.[23] Even though the majority of the studies described positive benefits, the review questioned the quality of the studies and expressed the need for more homogeneity and control in future studies in order to provide evidence for the use of neural mobilization as a therapeutic intervention.

Principles of Management

The principles of treatment are similar to those of any mobilization technique.[10]

- The intensity of the maneuver should be related to irritability of the tissue, patient response, and change in symptoms. The greater the irritability, the gentler the technique.
- Neurological symptoms of tingling or increased numbness should not last when the stretch is released.
- ***Neural tension technique.*** Application of the techniques requires positioning the trunk and extremity at the point of

tension (symptoms just begin), then either passively or having the patient actively moving one joint in the pattern in such a way as to stretch and then release the tension. Moving different joints in the pattern while maintaining the elongated position on the other joints changes the forces on the nerves.

- ***Neural glide technique.*** Positioning the individual is the same as with the tension technique (at point of tension), but the movement involves moving two joints in the chain, so the tension remains the same but the neural tissue glides proximally or distally. For example, once at the position of tension, perform elbow flexion simultaneously with cervical contralateral flexion, or wrist flexion simultaneously with elbow flexion to glide the median nerve proximally.
- The stretch force for both techniques is held for 15 to 20 seconds, released, and then repeated several times.
- After the therapist has performed several treatments and learned the tissue response, the patient is taught self-stretching.

CLINICAL TIP

If performed within the tolerance of the tissues, neural mobilization maneuvers may be used to prevent restrictive adhesions from developing in or around the nerve after an acute injury or surgery.

Precautions and Contraindications to Neural Tension Testing and Treatment

There is incomplete scientific understanding of the pathology and mechanisms that occur when mobilizing the nervous system.[10] Use caution with the stretch force; neurological symptoms of tingling or increased numbness should not last when the stretch is released. The clinician should always use caution and perform a thorough systems review and screening examination to rule out "red flag" conditions prior to neural tension testing and treatment.[11]

PRECAUTIONS:

- Know what other tissues are affected by the positions and maneuvers.
- Recognize the irritability of the tissues involved and do not aggravate the symptoms with excessive stress or repeated movements.
- Identify whether the condition is worsening and the rate of worsening. A rapidly worsening condition requires greater care than a slowly progressing condition.
- Use care if there is an active disease or other pathology affecting the nervous system.
- Watch for signs of vascular compromise. The vascular system is in close proximity to the nervous system and at no time should show signs of compromise when mobilizing the nervous system.

CONTRAINDICATIONS:

- Acute or unstable neurological signs
- Cauda equina symptoms related to the spine including changes in bowel or bladder control and perineal sensation
- Spinal cord injury or symptoms
- Neoplasm and infection

Neural Testing and Mobilization Techniques for the Upper Quadrant

Median Nerve (Fig. 13.13)

This maneuver is used when examining and treating symptoms related to median nerve distribution, problems with shoulder girdle depression (e.g., thoracic outlet syndrome), and carpal tunnel syndrome.[10]

Patient position and procedure: Begin with the patient supine; sequentially apply shoulder girdle depression, then slightly abduct the shoulder, extend the elbow, laterally rotate the arm, and supinate the forearm. Wrist, finger, and thumb extensions are then added; finally, the shoulder is taken into greater abduction. The full stretch position includes contralateral cervical side flexion. While maintaining the stretch position, move one joint at a time a few degrees in and out of the stretch position, using wrist extension and flexion or elbow flexion and extension, or perform the sliding technique by moving two joints simultaneously in the same direction.

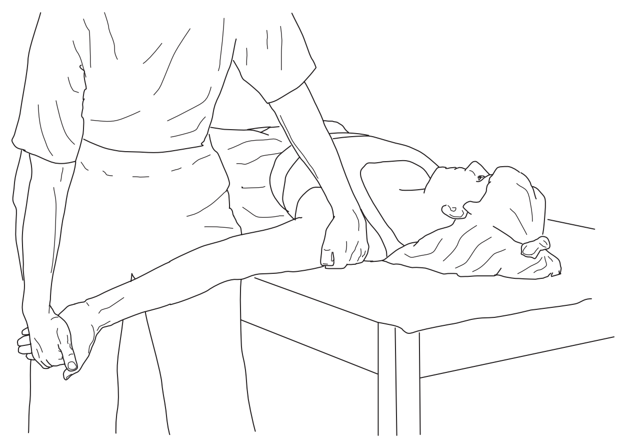

FIGURE 13.13 Position of maximum stretch on the median nerve includes shoulder girdle depression; shoulder abduction; elbow extension; shoulder external rotation and supination of the forearm; wrist, finger, and thumb extension; and finally contralateral cervical side flexion.

FOCUS ON EVIDENCE

Using ultrasound imaging, Coppieters and associates[13a] examined the longitudinal excursion of the median nerve, using several variations of cervical and elbow movements that caused either sliding or tensioning of the median nerve. For the sliding technique, elbow flexion and cervical side flexion were performed simultaneously in the same direction; for one

tensioning technique, elbow extension and cervical side flexion were performed simultaneously in opposite directions; and for four techniques, only one joint (elbow or neck) was moved after prepositioning the other joint.

Results showed significant differences in the amount of nerve movement with the various techniques ($P < .0001$). Greatest excursion occurred with the sliding technique when the two joints were moved in the same direction (10.2 +/ −2.8 mm); the smallest excursion occurred with the tensioning technique when the two joints were moved in opposite directions (1.8 +/ −4.0 mm). Techniques in which only one joint moved demonstrated larger excursions when the elbow moved (5.6 and 5.5 mm) than when the neck moved (3.3 and 3.4 mm). These tests were performed on healthy volunteers and therefore, cannot be generalized to therapeutic effects for patients with different pathologies affecting the median nerve.

Radial Nerve (Fig. 13.14)

This maneuver is important when examining and treating symptoms that are related to shoulder girdle depression, radial nerve distribution, and disorders such as tennis elbow and de Quervain's syndrome.[10]

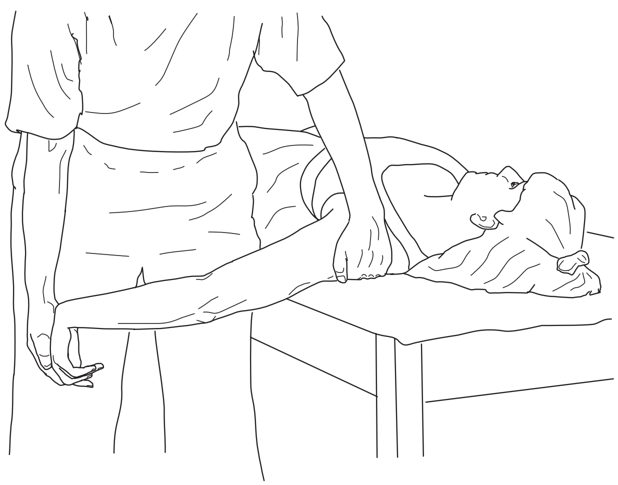

FIGURE 13.14 Position of maximum stretch on the radial nerve includes shoulder girdle depression; shoulder abduction; elbow extension; shoulder medial rotation and forearm pronation; wrist, finger, and thumb flexion; wrist ulnar deviation; and finally contralateral cervical side flexion.

Patient position and procedure: Begin with the patient supine; sequentially apply shoulder girdle depression, then slightly abduct the shoulder, extend the elbow, then medially rotate the arm and pronate the forearm. Keep the elbow in extension and add wrist, finger, and thumb flexion, and finally ulnar deviation of the wrist. The full stretch position includes contralateral side flexion of the cervical spine. While maintaining the stretch position, move one joint at a time a few degrees in and out of the stretch position, using wrist extension and flexion.

Ulnar Nerve (Fig. 13.15)

This maneuver is used when symptoms are related to the C-8 and T-1 nerve roots, lower brachial plexus, ulnar nerve, and disorders such as medial epicondylitis.[10]

FIGURE 13.15 Position of maximum stretch on the ulnar nerve includes shoulder girdle depression; shoulder external rotation and abduction; elbow flexion; forearm supination and wrist extension; and finally contralateral cervical side flexion.

Patient position and procedure: Begin with the patient supine. Sequentially apply wrist extension and forearm supination followed by elbow flexion (full range); then add shoulder girdle depression. Maintain this position and add shoulder lateral rotation and abduction. In the final position the patient's hand is near his or her ear with fingers pointing posteriorly. In the full stretch position, contralateral side flexion of the cervical spine is added. While maintaining the overall stretch position, move one joint at a time a few degrees in and out of the stretch position, such as elbow extension and flexion.

Neural Testing and Mobilization Techniques for the Lower Quadrant

Sciatic Nerve: Straight-Leg Raising with Ankle Dorsiflexion (Fig. 13.16)

Patient position and procedure: The patient is supine. Lift the lower extremity in the straight-leg raise (SLR) position and add ankle dorsiflexion. Several variations may be done; ankle dorsiflexion, ankle plantar flexion with inversion, hip adduction, hip medial rotation, and passive neck flexion.[10] The maneuver may also be performed long-sitting (slump-sitting position—see below) and side-lying. These various positions of the lower extremity and neck are used to differentiate tight or strained hamstrings from possible sites of restriction or nerve mobility in the lumbosacral plexus and sciatic nerve.[8,27,70] Changing positions of the ankle in conjunction with variations in the hip and knee positions are used to differentiate foot impairments, such as plantar fasciitis and tarsal tunnel syndrome.[1]

FIGURE 13.16 Position of stretch on the sciatic nerve includes straight-leg raising with adduction and internal rotation of the hip and dorsiflexion of the ankle.

FIGURE 13.17 Slump-sitting with neck, thorax, and low back flexed, knee extended, and ankle dorsiflexed just to the point of tissue resistance and symptom reproduction.

Once the position that places tension on the involved neurological tissue is found, maintain the stretch position and then move one of the joints a few degrees in and out of the stretch position, such as ankle plantarflexion and dorsiflexion or knee flexion and extension.

- Ankle dorsiflexion with eversion places more tension on the tibial tract.
- Ankle dorsiflexion with inversion places tension on the sural nerve.
- Ankle plantarflexion with inversion places tension on the common peroneal tract.
- Adduction of the hip while doing SLR places further tension on the nervous system, because the sciatic nerve is lateral to the ischial tuberosity; medial rotation of the hip while doing SLR also increases tension on the sciatic nerve (see Fig. 13.16).
- Passive neck flexion while doing SLR pulls the spinal cord cranially and places the entire nervous system on a stretch.
- Strain on the medial and lateral plantar nerves increases with toe extension and is larger with ankle dorsiflexion than plantarflexion.[1]

Slump-Sitting (Fig. 13.17)

Patient position and procedure: Begin with the patient sitting upright. Have the patient slump by flexing the neck, thorax, and low back. Apply overpressure to cervical spine. Dorsiflex the ankle and then extend the knee as much as possible to the point of tissue resistance and symptom reproduction. Release the overpressure on the spine and have the patient actively extend the neck to see if symptoms decrease. Increase and release the stretch force by moving one joint in the chain a few degrees, such as knee flexion and extension or ankle dorsiflexion and plantarflexion.

Femoral Nerve: Prone Knee Bend (Fig. 13.18)

Patient position and procedure: Prone with the spine neutral (not extended) and the hips extended to 0°. Flex the knee to the point of resistance and symptom reproduction. Pain in the low back or neurological signs (change in sensation in the anterior thigh) are considered positive for upper lumbar nerve roots and femoral nerve tension. Thigh pain could be rectus femoris tightness. It is important not to hyperextend the spine to avoid confusion with nerve root pressure from

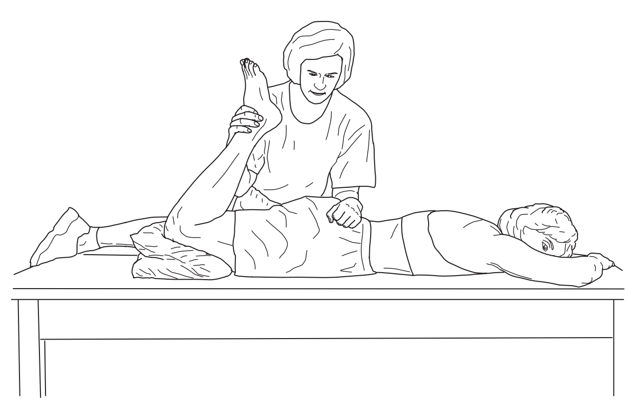

FIGURE 13.18 Position of stretch on the femoral nerve; prone lying with the spine neutral, hip extended to zero degrees, and knee flexed. It is important to maintain the spine in neutral and not allow it to extend.

decreased foraminal space or facet pain from spinal movement. Flex and extend the knee a few degrees to apply and release tension.

Alternate position and procedure: Side-lying with the involved leg uppermost. Stabilize the pelvis and extend the hip with the knee flexed until symptoms are reproduced. Maintain knee flexion, release, and apply tension across the hip by moving it a few degrees at a time.

Musculoskeletal Diagnoses Involving Impaired Nerve Function

Thoracic Outlet Syndrome

The thoracic outlet is the region along the pathway of the brachial plexus from just distal to the nerve roots exiting the intervertebral foramen to the lower border of the axilla (Fig. 13.19). The outlet is bordered medially by the scalenus anterior, medius, and posterior and the first rib; posteriorly by the upper trapezius and scapula; anteriorly by the clavicle, coracoid, pectoralis minor, and deltopectoral fascia; and laterally by the axilla. The plexus enters the outlet between the scalenus anterior and medius; the subclavian artery runs posterior to the scalenus anterior; and the subclavian vein runs anterior to the scalenus anterior. The blood vessels join the brachial plexus and course together under the clavicle, over the first rib, and under the coracoid process posterior to the pectoralis minor. Vascular and/or upper extremity neurological symptoms that are not consistent with nerve root or peripheral nerve dermatome and myotome patterns should lead the therapist to suspect thoracic outlet problems.[41]

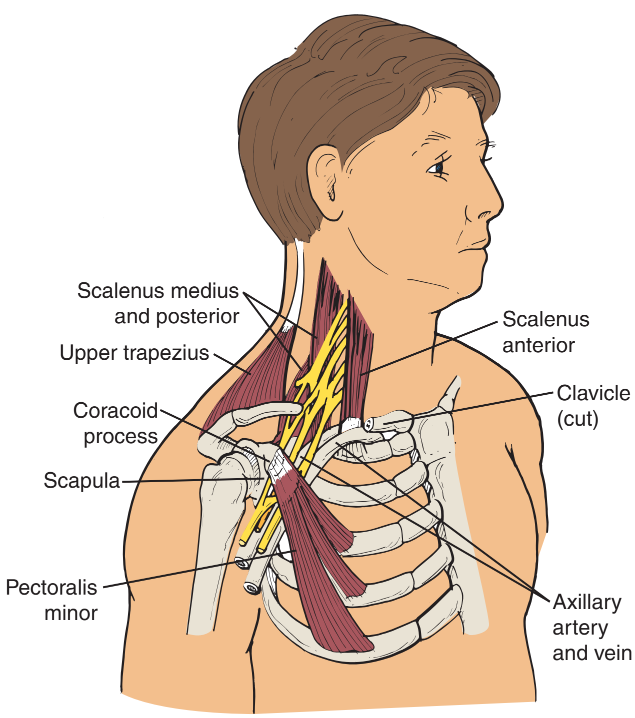

FIGURE 13.19 Region of the thoracic outlet bordered medially by the scalene muscle and first rib; posteriorly by the upper trapezius and scapula; anteriorly by the clavicle, coracoid, pectoralis minor, and deltopectoral fascia; and laterally by the axilla.

Related Diagnoses

Thoracic outlet syndrome (TOS) encompasses a variety of clinical problems in the shoulder girdle region. The diagnosis itself is controversial because of the clinical complexity and variability in presentation that involves upper extremity neurological and vascular symptoms, including pain, paresthesia, numbness, weakness, discoloration, swelling, loss of pulse, ulceration, gangrene, and, in some cases, Raynaud's phenomenon. Patients also complain of headaches, which may be related to posture, tension, or vascular compromise. Diagnoses that have been used to describe TOS include cervical rib, scalenus anticus syndrome, costoclavicular syndrome, subcoracoid-pectoralis minor syndrome, droopy shoulder syndrome, and hyperabduction syndrome.[17,53,66,67,74] Commonly accepted medical diagnoses include:

- ***Neurogenic TOS—true TOS.*** This condition is rare. The patient presents with some anatomical abnormality, such as cervical rib or elongated C7 transverse process. The patient describes paresthesias and pain along the medial border of the arm and experiences muscle weakness; there is atrophy in the intrinsic muscles of the hand. There are also positive electromyographic (EMG) findings. The condition is often misdiagnosed as carpal tunnel syndrome.
- ***Nonspecific "symptomatic" neurogenic TOS.*** This condition is similar to true TOS, but there are no anatomical abnormalities detected by radiography, no muscle atrophy, and no EMG findings. Often, there is a postural component. Most TOS complaints fall into this category.
- ***Vascular syndromes—arterial.*** In some cases, there is a small incidence of arterial compression. This condition is rare and is usually the result of structural abnormalities such as cervical rib. There is compression of the artery with arm motion, especially overhead usage. If the arm fatigues with overhead usage, the person may have to adapt work habits that avoid risk from repetitive trauma to the artery.
- ***Vascular syndromes—venous.*** Compression of the subclavian vein does not typically occur in TOS; venous symptoms would be from some other cause, such as thrombosis. Acute thrombosis (sudden, painful swelling with bluish discoloration of the arm) is usually dealt with medically, but the therapist should always be suspicious of unexplained swelling of the arm. Effort thrombosis could occur from sudden maximal arm use, or there could be insidious onset of swelling with prolonged use. If these occur, the patient's physician should be contacted.

Etiology of Symptoms

Walsh[74] has identified three causative factors for TOS that could be interrelated or exist separately: compressive neuropathy, faulty posture, and entrapment.

- ***Compressive neuropathy.*** Compression of the neurovascular structures can occur if there is a decrease in the size of the area through which the brachial plexus and subclavian vessels pass. Compression can result from muscle hypertrophy in the scalenes or pectoralis minor; anatomical anomalies, such as cervical rib or fractured clavicle; adaptive shortening of fascia; or a space-occupying lesion.
- ***Faulty posture.*** Changes in posture, particularly forward head with increased thoracic kyphosis, protracted scapulae, and forward shoulders, narrow the spaces through which the neurovascular structures pass. Specifically, adaptive shortening of the scaleni and pectoralis minor muscles can potentially compress the neurovascular tissues or can cause repetitive trauma and adhesions with overuse.[49] If the angle of the clavicle falls below the level of the sternoclavicular joint, the shoulder girdle causes traction on the plexus.[66] In addition, the clavicle can compress the neurovascular structures against the first rib.

Other contributing factors to postural stresses include hypertrophy of breast tissue leading to postural fatigue or pressure from undergarment support straps and carrying a heavy briefcase, suitcase, or shoulder purse that causes pressure across the shoulder girdle, fatigue in the scapular stabilizers, or traction across the shoulder girdle tissues.

FOCUS ON EVIDENCE

A study reported by Pascarelli and Hsu[54] of 485 patients with work-related upper quarter pain and symptoms indicated that 70% of patients displayed posture-elated neurogenic TOS as a key factor in a series of cascading events, including 78% with protracted shoulders, 71% with forward head posture, 50% with hyperlaxity of fingers and elbows, 20% with sympathetic dysfunction, 64% with cubital tunnel, 60% with medial epicondylitis, 70% with peripheral muscle weakness, and other miscellaneous conditions such as carpal tunnel syndrome. Wood and Biondi[80] pointed out that, among 165 patients with TOS, 44% also had compression of a nerve distally, most commonly in the carpal tunnel (41 cases).

A surgical study reported findings that pathological adhesions of the brachial plexus to the scalenus muscle led to nerve fiber distraction as the mechanism behind the symptoms and suggested that the restrictive adhesions were directly related to long-standing postural deviations and myofascial pain syndrome.[15]

- ***Entrapment of neural tissue from scar tissue or pressure.*** Entrapment affects the ability of nerve tissue of the brachial plexus to tolerate tension as it courses through the various tissues in the thoracic outlet. A possible explanation was offered in a review article by Crotti[16] wherein the pain-immobility-fibrosis loop that occurs after trauma (e.g., following an acceleration-extension motor vehicle injury) leads to the development of adhesions, which cause or perpetuate TOS symptoms. The Halstead test[45] and the upper limb tension test for the median nerve[10] (see Fig. 13.14) place the brachial plexus and median nerve on a stretch and with symptoms may indicate restricted nerve gliding. The Halstead test also may obliterate the radial pulse indicating vascular entrapment. Wilson and associates[79] described a cadaver study that demonstrated tension placed on the subclavian artery with either ipsilateral or contralateral side-bending of the cervical spine during the TOS testing maneuvers. They suggested that this could be the source of pain or tension symptoms even prior to signs of vascular pathology (decreased pulse, pallor, skin temperature).[79]

Contributing factors in the development of TOS are summarized in Box 13.7.

BOX 13.7 Summary of Contributing Factors to Thoracic Outlet Syndrome

There is wide latitude of motion in the various joints of the shoulder complex that may result in compression or impingement of the nerves or vessels in TOS.

- *Postural variations*, such as a forward head or round shoulders, lead to associated muscle shortening in the scalene, levator, subscapularis, and pectoralis minor muscles and a depressed clavicle.
- *Postural stress,* such as carrying a heavy suitcase, brief case, or purse, can place stress across the shoulder girdle, creating pressure in the thoracic outlet or traction on the brachial plexus.
- *Respiratory patterns* that continually use the action of the scalene muscles to elevate the upper ribs lead to hypertrophy of these muscles. Also, the elevated upper ribs decrease the space under the clavicle.
- *Congenital factors,* such as an accessory rib, a long transverse process of the C-7 vertebra, or other anomalies in the region, can reduce the space for the vessels. A traumatic or arteriosclerotic insult can also lead to TOS symptoms.
- *Traumatic injuries,* such as clavicular fracture or subacromial dislocations of the humeral head, can injure the plexus and vessels, leading to TOS symptoms.
- *Hypertrophy or scarring* in the pectoralis minor muscles can lead to TOS symptoms.
- *Injuries* that result in inflammation, scar tissue formation, and adhesions can restrict nerve tissue mobility when tension is placed on the nerve. This may occur anywhere from the intervertebral foramina at the spine to the distal-most portion of the peripheral nerve. There are nerve tension signs from restricted mobility.

Sites of Compression or Entrapment

There are three primary sites for compression or entrapment of the neurovascular structures that lead to tension or compression signs.[74]

- **Interscalene triangle:** *bordered by the scalenus anterior and medius muscles and the first rib.* If these muscles are hypertrophied, tight, or have anatomical variations, they may compress the proximal portion of the brachial plexus normal mobility of the neural tissues with head and arm movements.

Symptoms from dysfunction in this area are reproduced with Adson's maneuver, which stretches the scalene muscles and places tension on the nerves. If the artery is compressed, there is also a decreased pulse.[45] Palpation of the scalene muscles may also provoke symptoms.

- **Costoclavicular space:** *between the clavicle superiorly and the first rib inferiorly.* Compression of the neurovascular bundle can occur between the clavicle and first rib, especially if the clavicle is depressed for periods of time, as occurs when carrying a heavy suitcase or shoulder bag or with a faulty, slouched posture. A fractured clavicle or anomalies in the region can also lead to symptoms. An elevated first rib, which can occur with first rib subluxation or upper thoracic breathing (as with asthma or chronic emphysema), also narrows the costoclavicular space.

Symptoms caused by a depressed clavicle are reproduced when the shoulders are retracted and depressed as with the Military Brace Test.[45] If a patient is asked to take in a breath while in this posture and symptoms are reproduced, the rib elevation is causing the symptoms. The mobility of the clavicle and first rib should also be tested.

- **Axillary interval:** *between the anterior deltopectoral fascia, the pectoralis minor, and the coracoid process.* Compression or restricted movement of the neurovascular structures may occur in this region if the pectoralis minor is tight owing to faulty posture with the scapula tipped forward or to repetitive overuse.

Holding the arms in an elevated position places a stretch on the lower branches of the brachial plexus and blood vessels. If there is poor neurovascular mobility and tension is placed on the brachial plexus, a patient experiences reproduction of symptoms when the arm is abducted. In addition, if the person repeatedly opens and closes his hand and there is increased ischemic pain (Roos test),[45] there is vascular compromise. Palpation pressure against the pectoralis minor reproduces the neurological symptoms if the muscle is tight.

Common Structural and Functional Impairments in TOS

- Intermittent brachial plexus and vascular symptoms of pain, paresthesia, numbness, weakness, discoloration, and swelling
- Muscle length-strength imbalance in the shoulder girdle with tightness in anterior and medial structures and weakness in posterior and lateral structures
- Faulty postural awareness in the upper quarter
- Poor endurance in the postural muscles
- Shallow respiratory pattern characterized by upper thoracic breathing
- Poor clavicular and anterior rib mobility
- Nerve tension symptoms when the brachial plexus is placed on a stretch

Common Activity Limitations and Participation Restrictions (Functional Limitations/Disabilities)

- Sleep disturbances that could be from excessive pillow thickness or arm posture
- Inability to carry briefcase, suitcase, purse with shoulder strap, or other weighted objects on the involved side
- Inability to maintain prolonged overhead reaching position
- Inability to do sustained computer or desk work, cradle a telephone receiver between head and involved shoulder, or drive a car for prolonged periods

Nonoperative Management of TOS

If the symptoms demonstrate that there is inflammation, treatment is first directed at eliminating the provoking mechanism and controlling the inflammation. Conservative interventions usually precede surgery. The primary emphasis of management is to decrease the mechanical pressure by increasing the mobility of tissues in the thoracic outlet region, preventing recurrence of the compression loads by correcting the postural alignment, and developing endurance to maintain correct posture.[3,40,74]

A program is developed utilizing interventions that specifically address the presenting impairments (Box 13.8). Also, secondary or associated complaints, such as myofascial trigger points, glenohumeral joint pathology, cervical pathology, or distal peripheral neuropathies, should be identified and appropriate interventions incorporated into the program.[74] Consider the following precautions and interventions.

PRECAUTIONS: Shoulder girdle exercises may cause worsening of symptoms in some patients; or they may be progressing favorably, then symptoms worsen. Worsening of neurological or vascular symptoms may indicate axonal disruption or vascular compromise. Refer the patient to his or her physician; surgical decompression may be indicated.

- ***Patient education.*** Teach the patient how to modify or eliminate provoking postures and activities and provide a home exercise program that includes flexibility, muscle performance, and postural exercises (see Chapter 14). Emphasize the importance of compliance to reduce the stresses on the nerve and vascular structures.

BOX 13.8 Summary of Guidelines for Management of Thoracic Outlet Syndrome

Educate the patient.

- Teach posture correction.
- Teach how to modify provoking stresses.
- Teach safe exercises for home exercise program.

Correct impaired posture.

- See Chapter 14

Mobilize restricted neurological tissue.

- Nerve mobilization techniques if testing is positive for restricted mobility

Mobilize restricted joints, connective tissue, and muscle.

- Tissue-specific manual techniques to restricted structures if testing is positive for restricted mobility
- Self-stretching exercises for restricted muscle flexibility

Improve muscle performance.

- Develop control and endurance in postural muscles.
- Progress strengthening exercises.

Correct faulty breathing patterns.

- Relax upper thorax.
- Teach abdominal diaphragmatic or bi-basalar breathing patterns.

Progress functional independence.

- Involve patient in all aspects of program.

- ***Nerve tissue mobility.*** Use nerve mobilization maneuvers if nerve tension tests are positive.[78] These are described earlier in this chapter.
- ***Joint, muscle, and connective tissue mobility.*** Use manual and self-stretching techniques to address any mobility impairments. Restricted joint mobility might be present in the glenohumeral, sternoclavicular, or first costotransverse articulations. Common muscle restrictions with an impaired postural component include but are not limited to the scalene, levator scapulae, pectoralis minor, pectoralis major, anterior portion of the intercostals, and short suboccipital muscles. Stretching exercises to increase mobility in these muscles are described in Chapter 14 (section on posture exercises) and Chapter 17.
- ***Muscle performance.*** Develop a program to improve control and endurance in the postural muscles. Common weaknesses include but are not limited to scapular adductors and upward rotators, shoulder lateral rotators, deep anterior throat cervical flexor muscles, and thoracic extensors. Identification of postural exercises to improve muscle performance are listed in Chapter 14 (section on posture exercises).
- ***Respiratory patterns and elevated upper ribs.*** If the patient tends to use apical breathing patterns and has increased tension in the scalene muscles, teach abdominodiaphragmatic or bi-basilar breathing patterns and relaxation of the upper thorax.
- ***Functional independence.*** Increase patient awareness and ability to manage symptoms through education. Have patients actively involved in all aspects of their program and interventions.

Carpal Tunnel Syndrome

The carpal tunnel is a confined space between the carpal bones dorsally and the transverse carpal ligament (flexor retinaculum) volarly (Fig. 13.20). In this region, the median nerve is susceptible to pressure as it courses through the tunnel with the extrinsic finger flexor tendons on their way into the hand. Carpal tunnel syndrome (CTS) is characterized by the sensory loss and motor weakness that occur when the median nerve is compromised in the carpal tunnel. Anything that decreases the space in the carpal tunnel or causes the contents of the tunnel to enlarge could compress or restrict the mobility of the median nerve, causing a compression or traction injury, ischemia, and neurological symptoms distal to the wrist.[26,30,47]

Etiology of Symptoms

Etiology is multifactorial, including both local and systematic factors.[26] Local factors include synovial thickness and scarring in the tendon sheaths (tendinosis) or irritation, inflammation, and swelling of the tendons (tendinitis) as a result of repetitive or sustained wrist flexion, extension, or gripping activities. Because of this, CTS is frequently classified as a cumulative trauma or overuse syndrome. Swelling in the wrist area due to local trauma (e.g., a fall or blow to the wrist, with or without a carpal or distal radius fracture), carpal dislocation, or osteoarthritis, or systematic factors, such as pregnancy (hormonal changes and water retention), rheumatoid arthritis, or diabetes, could decrease the carpal tunnel space. Awkward wrist postures (flexion or extension), compressive forces from sustained equipment usage, and vibration against the carpal tunnel could also lead to median nerve compression and trauma.[5,26]

Examination

In a recent review on the sensitivity and specificity of the various tests used when screening for CTS, MacDermid and Doherty[43] summarized the key signs and symptoms that increase the probability of diagnosing CTS.

History. The patient describes sensory changes in the median nerve distribution of the hand (excluding the palm, which is innervated by the palmar cutaneous branch of the median nerve arising proximal to the carpal tunnel) and nocturnal numbness and pain that is relieved by flicking the wrists.

Positive clinical findings. Depending on severity, there may be atrophy of the thenar eminence and an ape-hand posture (see Table 13.1) Results of tests include thenar muscle weakness, positive Phalen's test (sustained wrist flexion), loss of two-point discrimination, and positive Tinel's sign (tapping

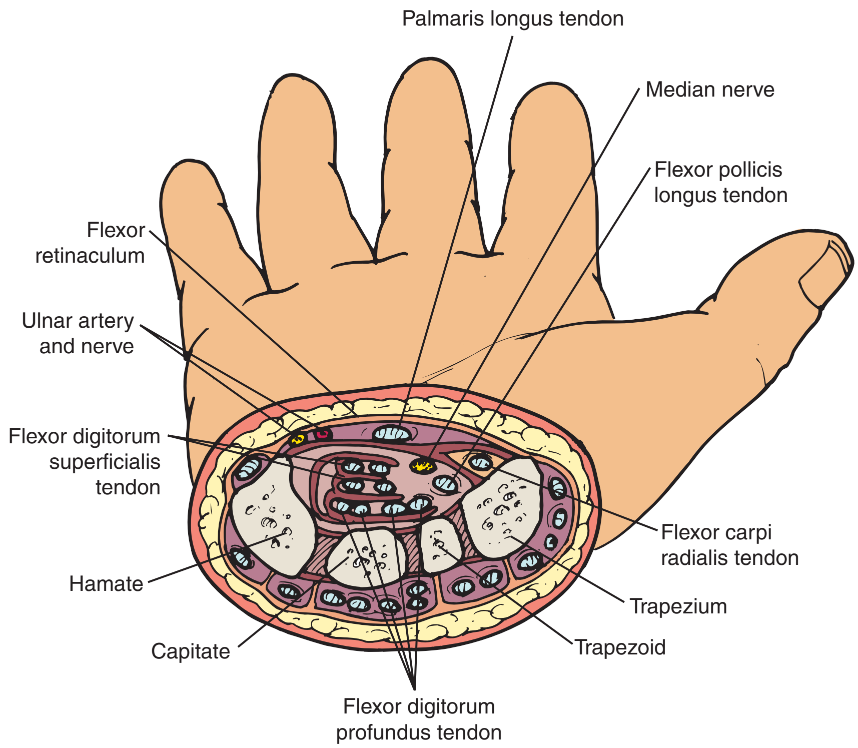

FIGURE 13.20 Boundaries of the carpal tunnel.

the median nerve).[45] Electrophysiological studies (nerve conduction and electromyography) are used to assist with a differential diagnosis.[26]

Associated areas to clear. Because there can be other causes of median nerve symptoms, such as tension, compression, or restricted mobility of the nerve roots in the cervical intervertebral foramen, of the brachial plexus in the thoracic outlet, or of the median nerve as it courses through tissues in the forearm region (pronator syndrome and anterior interosseous nerve syndrome),[39] each of these sites must be examined to rule them out or determine if any is the cause of the median nerve symptoms[31,39] (see Fig. 13.5).

Double crush injury. With nerve irritability, it is possible to develop what is known as a double crush injury[10,42,44,49] in which the nerve develops symptoms at other areas along its course as well as at the primary site. Wood and Biondi[80] reported that 41 of 165 patients with TOS also had CTS, which they attributed to the lessened ability of the nerves to withstand distal compression when irritated proximally. In contrast, Seror[59,60] reported a lack of evidence supporting a relationship between unambiguous CTS in true neurogenic TOS (< 1/100), although disputed neurogenic TOS was frequently found (mild to moderate clinical symptoms and signs) even when there were no significant findings on electrodiagnostic tests.[59] Fernández-de-Las-Peñas and colleagues[24] demonstrated increased mechanical nerve pain sensitivity of the entire median nerve in subjects with CTS, as measured by pressure pain thresholds. They suggested that there is both central and peripheral sensitization of the entire nerve trunk in this condition.

Common Structural and Functional Impairments

- Increasing pain in the hand with repetitive use
- Progressive weakness or atrophy in the thenar muscles and first two lumbricals (ape hand deformity)
- Tightness in the adductor pollicis and extrinsic extensors of the thumb and digits 2 and 3
- Irritability or sensory loss in the median nerve distribution (see Fig. 13.5)
- Possible decreased joint mobility in the wrist and metacarpophalangeal joints of the thumb and digits 2 and 3
- Sympathetic nervous system changes may develop
- Faulty forward head posture and decreased cervical ROM[19]

Common Activity Limitations and Participation Restrictions (Functional Limitations/Disabilities)

- Decreased prehension in tip-to-tip, tip-to-pad, and pad-to-pad activities requiring fine neuromuscular control of thumb opposition, such as buttoning clothes and manipulating small objects
- Avoidance of using the area of the hand where there is decreased sensation
- Inability to perform provoking sustained or repetitive wrist motion, such as cashier checkout scanning, assembly line work, fine tool manipulation, or typing

Nonoperative Management of CTS

In patients with mild to moderate symptoms, conservative intervention is directed toward minimizing or eliminating the causative factor[43,51] (Box 13.9). Considerations include:

- ***Nerve protection.*** Initially, the wrist may have to be splinted to provide rest from the provoking activity. Splint the wrist in the neutral position, so there is minimal pressure in the tunnel.[47]
- ***Activity modification and patient education.*** Identify faulty wrist, cervical, and upper extremity postures and activities.
  - *Activity modification.* Modify activities to keep the wrist in neutral and to reduce forceful prehension.
  - *Education.* Teach the patient about the mechanisms of compression and their effect on the circulation and nerve pressure as well as how to modify or eliminate provoking postures and activities. Also, instruct the patient to observe areas with decreased sensitivity to avoid tissue injury (see Box 13.6).
  - *Home exercise program.* Teach the patient safe exercises for a home exercise program. Emphasize the importance of compliance to reduce stresses on the nerve and tendinous structures. Incoroporate postural exercises for the spinal and shoulder girdle regions if indicated.

BOX 13.9 Summary of Guidelines for Nonoperative Management of Carpal Tunnel Syndrome

Protect the nerve

- Splint wrist in neutral
- Protect areas in decreased sensitivity

Modify activity and educate the patient

- Teach patient about provoking activities and how to modify them
- Teach safe exercises for home exercise program
- Teach patient how to protect areas of decreased sensitivity in the hand (see Box 13.5)

Mobilize restricted joints, connective tissue, and muscle/tendon

- Mobilize carpals if restricted
- Tendon gliding exercises
- Median nerve mobilization exercises

Improve muscle performance

- Gentle multi-angle muscle setting
- Progress to resistance and endurance
- Fine-finger dexterity

Progress functional independence

- Involve patient in all aspects of program
- Self monitoring of symptoms

- ***Mobility techniques***
  - *Joint mobilization.* If there is restricted joint mobility, mobilize the carpals for increased carpal tunnel space. See Figure 5.39 and its description in Chapter 5.
  - *Tendon-gliding exercises.* Teach the patient tendon-gliding exercises for mobility in the extrinsic tendons; they should be performed gently to prevent increased swelling. See Figure 19.17 and the description in the exercise section of Chapter 19.
  - *Median nerve mobilization.*[10,58] The six positions for median nerve mobilization in the wrist and hand are illustrated in Figure 13.21. Begin with position A and progress to each succeeding position until the median nerve symptoms just begin to be provoked (tingling). That is the maximum position to use. Sustain that position for 5 to 30 seconds without making the symptoms worse. Then alternate between that position and the preceding position. When the patient can be moved into that position without symptoms, progress to the next stretch position and repeat the mobilizing routine. The mobilization exercise should be done three or four times per day so long as symptoms are not exacerbated.

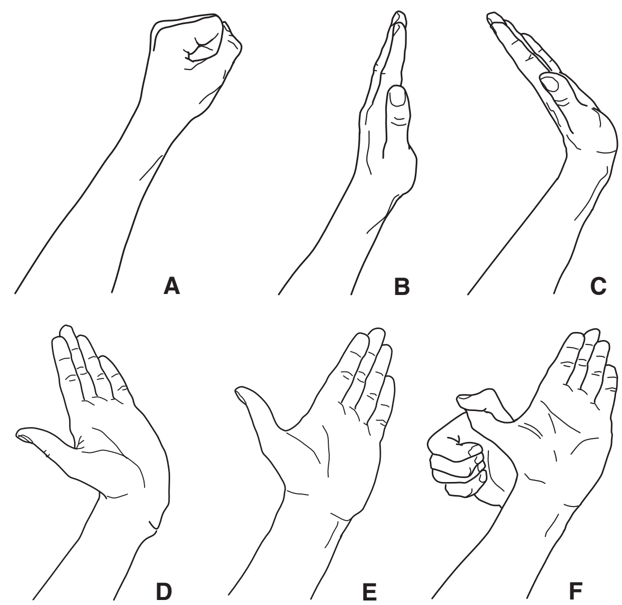

FIGURE 13.21 Positions for median nerve glides and mobilization in the hand: **(A)** wrist neutral with fingers and thumb flexed; **(B)** wrist neutral with fingers and thumb extended; **(C)** wrist and fingers extended, thumb neutral; **(D)** wrist, fingers, and thumb extended; **(E)** wrist, fingers, and thumb extended and forearm supinated; **(F)** wrist, fingers, and thumb extended, forearm supinated, and thumb stretched into extension.

Additional median nerve mobilization techniques, including the entire upper extremity and neck, can be added if symptoms warrant. (See Figure 13.14 and the description of principles earlier in this chapter under upper limb tension.)

FOCUS ON EVIDENCE

A study by Rozmaryn and colleagues[58] documented a significant improvement in symptoms in patients treated conservatively with tendon-gliding and median nerve-gliding exercises. Only 43% of patients in the experimental group who performed the nerve mobilization exercises underwent subsequent surgical release of the carpal tunnel compared to 71% of the control group. Bialosky and associates[7] compared a group treated with median nerve mobilization techniques and a group with a sham technique that did not place the entire median nerve on a stretch; wrist and finger flexion/extension was consistent in both groups. A series of tests was conducted at the beginning and after 3 weeks of treatment (two times per week for up to six treatments); both groups received splints to wear at night. There was no control group. The only significant difference between groups was a reduction of temporal summation of symptoms in the group receiving the stretch mobilization to the median nerve. The authors speculated that improved outcomes in most of the measures seen in both groups were related to receiving manual therapy and were independent of the specific mechanical force on the median nerve.[7]

- ***Muscle performance***
  - *Gentle multiple-angle muscle-setting exercises.* Initially, gentle muscle-setting exercises are the only resistance exercises done. It is important that they do not provoke symptoms.
  - *Strengthening and endurance exercises.* Add dynamic strengthening and endurance exercises when symptoms are not increased with isometric exercises and there is full tendon- and nerve-gliding without symptoms or edema. Utilize exercises that prepare the patient for a return to functional activities.
  - *Speed, coordination, endurance, and fine finger dexterity*. Emphasize these activities when the symptoms are no longer provoked. Utilize activities that develop tip-to-tip and tip-to-pad prehension in order to improve use of the thenar muscles as well as areas of the skin that may have decreased sensation.
- ***Functional independence.*** Teach the patient how to monitor his or her hand for recurrence of symptoms and the provoking factors and how to modify activities to decrease nerve injury. Usually, sustained wrist flexion, ulnar deviation, and repetitive wrist flexion and extension combined with gripping and pinching are the most aggravating motions.

FOCUS ON EVIDENCE

In a Cochrane review of 21 trials involving 884 people, a hand brace significantly alleviated symptoms of CTS after 4 weeks; in one trial involving 21 people, symptoms were significantly diminished after 3 weeks with carpal bone mobilization (compared to no intervention). Other evidence supported the use of oral steroids, ultrasound, and yoga.[51]

Surgical and Postoperative Management for CTS

If conservative measures do not relieve the nerve symptoms or the neurological symptoms are severe (persistent numbness, weakness, pain, decreased functional use of the hand),[43] surgical decompression involving transaction of the transverse carpal ligament is performed to increase the volume of the carpal tunnel and relieve the compressive forces on the median nerve. Also, any scar tissue is excised. Surgery may be an open carpal tunnel release or endoscopically assisted carpal tunnel release.[5,26] Therapy may be initiated after surgery if there are restrictions or muscle weakness. Use exercise and mobilization techniques that deal with the impairments and functional loss (see Box 13.8).

Pain in the thenar and hypothenar eminences may result from the release and flattening of the palmar arch (pillar pain). Immediately after surgery, there is loss of the wrist pulley in the long finger flexor system due to release of the flexor retinaculum. The wrist may be immobilized 7 to 10 days postoperatively in slight extension with the fingers free to move. Time must be allowed for healing to prevent bowstringing of the flexor tendons at the wrist.

FOCUS ON EVIDENCE

A study by Cook and associates[12] looked at the value of splinting the wrist after surgery versus initiating ROM exercises on the first postoperative day with 50 consecutive patients and concluded that splinting the wrist following open release was detrimental. The primary concern is preventing bowstringing of the extrinsic flexor tendons, and therefore, the authors recommended exercising the fingers and wrist separately.[12]

Maximum Protection Phase

Usually a bulky dressing or splint is used following surgery. When allowed, remove the protective splinting during therapy.

PRECAUTION: Avoid active wrist flexion past neutral as well as active finger flexion with the wrist flexed during the first 10 days after surgery. Use extreme caution for up to 3 weeks postoperatively to prevent bowstringing of the flexor tendons through the flexor retinaculum.

- ***Patient education.*** Educate the patient on expectations for recovery. The impairments of decreased strength in grip and pinch as well as pillar pain should resolve within 3 to 6 months.[47] This is related to the changed length-tension relationship of the thenar muscles due to cutting the transverse carpal ligament. Neurological symptoms should resolve with time, with light touch returning first.[47]
- ***Wound management, control of edema and pain.***
- ***Active tendon-gliding and nerve-gliding exercises.*** Tendon-gliding (see Fig. 19.17) and nerve-gliding (see Fig. 13.21) exercises are important to prevent adhesion formation from restricting motion in the carpal tunnel. Include

forearm supination and elbow extension as nerve symptoms allow.[5,56]

- ***Exercises***
  - Active finger and thumb flexion/extension, abduction/adduction, and thumb opposition with the wrist stabilized in moderate wrist extension.
  - Active wrist extension; this may be combined with passive wrist flexion with the splint removed.
  - Active radial and ulnar deviation of the wrist (with the splint removed and the wrist supported in slight extension), pronation and supination of the forearm, and all shoulder and elbow motions.

Moderate and Minimum Protection Phases

Sutures are usually removed around the 10th to 12th postoperative day, and more active treatment is allowed.[56] The patient should be able to return to full activity by 6 to 12 weeks. Impairments may include residual weakness and sensory deficits, persistent edema, limited motion, hypersensitivity, and pain.

Suggested interventions include:

- ***Scar tissue mobilization.*** Use soft tissue mobilization to the palmar fascia and scar.
- ***Progressive stretching and joint mobilization of restricted tissue.*** If restricted, lengthen the abductor pollicis brevis and opponens pollicis. Mobilize restricted tendons or nerve tissue (same techniques as described previously except with a stretch force).
- ***Muscle performance.*** Begin strengthening exercises 4 weeks after surgery with isometric exercises. Progress to grip and pinch exercises by 6 weeks. Emphasize strength, coordination, and endurance toward functional goals. Wrist and hand exercises are described and illustrated in detail in Chapter 19.
- ***Dexterity exercises.*** Begin as soon as signs of motor recovery occur. Suggestions include picking up small objects using pad-to-pad, tip-to-tip, and tip-to pad prehension patterns; turning over cards; stacking checkers; writing; and holding the perimeter of a jar lid and having the thumb move around the edge in a circumduction motion.
- ***Sensory stimulation and discriminative sensory reeducation.*** Desensitization of hypersensitive skin is a priority. As the nerve recovers, help desensitize and reprogram awareness.[61] These techniques were described earlier in the chapter. Educate the patient about the progression of nerve recovery such that an area that had absence of sensation will have increased sensitivity and pain as it recovers. Symptoms usually subside within 1 to 6 months.

FOCUS ON EVIDENCE

A recent Cochrane database systems review analyzed surgical versus nonsurgical treatment for CTS and, based on the evidence, concluded that surgical treatment relieves symptoms significantly better than splinting, and that the long-term outcomes favored surgical intervention.[72] The study did not include patients with mild symptoms.

Ulnar Nerve Compression in Tunnel of Guyon

Entrapment of the ulnar nerve in the Tunnel of Guyon, also referred to as the Guyon Canal or ulnar tunnel, is second only to entrapment at the elbow. There are three sites (zones) where entrapment can occur.[65]

- Zone 1 is proximal to the bifurcation of the nerve; compression causes combined motor and sensory loss.
- Zone 2 is just distal to the bifurcation of the nerve; compression causes loss of motor function in ulnar-innervated muscles in the hand.
- Zone 3 encompasses the sensory branch; compression causes sensory loss to the hypothenar eminence, small finger, and part of ring finger.

Etiology of Symptoms

Injury or irritation of the ulnar nerve in the tunnel between the hook of the hamate and pisiform is the result of sustained pressure, such as prolonged handwriting or leaning forward onto extended wrists while biking; from synovial inflammation due to repetitive use of the gripping action of the fourth and fifth fingers, as with knitting, tying knots, or using pliers and staplers; or from trauma, such as falling on the ulnar border of the wrist (with or without a fracture to the hook of the hamate); or from a space-occupying lesion, such as a ganglion or aneurysm of the ulnar artery.[65]

Examination

History. The patient describes sensory symptoms in the little finger and ulnar side of the ring finger and may complain of fatigue or weakness in the hand with repetitive motions and difficulty with some activities, such as opening jars or turning doorknobs.

Positive clinical findings. Depending on severity, there may be atrophy of the hypothenar eminence and intrinsic muscles and a partial claw hand posture (see Table 13.1). Results of tests include intrinsic muscle weakness, positive Tinel's sign over the tunnel of Guyon (tapping ulnar nerve).

Associated areas to clear. There can be other causes of ulnar nerve symptoms, such as tension, compression, or restricted mobility of the nerve roots in the cervical intervertebral foramen, the brachial plexus in the thoracic outlet, or the ulnar nerve as it courses through the bicipital groove; or there could be impingement between the heads of the flexor carpi ulnaris muscle. Therefore, each of these sites must be examined to rule out or determine if any is the cause of the symptoms[49,65] (see Fig. 13.6). In addition, with nerve irritability it is possible to develop what is known as a double crush injury,[10] so the nerve develops symptoms at other areas along its course as well as at the primary site.

Common Structural and Functional Impairments

- Pain and paresthesia along the ulnar side of the palm of the hand and digits in the distribution of the ulnar nerve (see Fig. 13.6)
- Progressive weakness or atrophy in the intrinsic muscles innervated by the ulnar nerve
- Restricted mobility in the extrinsic finger flexor and extensor muscles
- Possible adhesions and restricted mobility of the pisiform

Common Activity Limitations and Participation Restrictions (Functional Limitations/Disabilities)

- Decreased grip strength
- Fatigue in the hand with repetitive or sustained activities
- Inability to use fourth and fifth digits for spherical or cylindrical power grips
- Decreased ability to perform provoking activity

Nonoperative Management

- Follow the same guidelines as for CTS. Modify the provoking activity, avoid pressure to the base of the palm of the hand, and provide rest with a cock-up splint.
- Ulnar nerve mobilization: Move the wrist into extension and radial deviation, then apply overpressure stretch into extension against the ring and little finger. Include forearm pronation and elbow flexion to move the nerve in a proximal direction. To test and mobilize the entire ulnar nerve, see Figure 13.15.

Surgical Release and Postoperative Management

If the patient's symptoms do not improve with 6 to 12 weeks of conservative treatment, or if there is progressive paralysis, long-standing muscle wasting and clawing of the digits, surgical release of the ulnar tunnel is performed.[65] After release, the wrist is immobilized 3 to 5 days; then treatment begins with gentle ROM. Follow the same guidelines as with carpal tunnel surgery but with ulnar nerve mobilization techniques.

Complex Regional Pain Syndrome: Reflex Sympathetic Dystrophy and Causalgia

Reflex sympathetic dystrophy (RSD) and causalgia are former diagnoses that are now classified as complex regional pain syndromes I and II, respectively (CRPS type I and CPRS type II) (Box 13.10). This revised taxonomic system was developed by a consensus conference in 1993 to clarify confusion about the meaning and interpretation of the previous diagnoses.[35,64,73] Basically, this is a grouping of complex painful disorders that develop as a consequence of trauma affecting the extremities with or without an obvious nerve lesion.[4,29]

Related Diagnoses and Symptoms

Common synonyms used in the past for RSD include shoulder-hand syndrome, Sudeck's atrophy, causalgia, posttraumatic dystrophy, reflex neurovascular dystrophy, traumatic angiospasm or vasospasm, and sympathetically maintained pain (SMP).[2,29,35,64,73] SMP is frequently a component of CRPS but is not a distinct diagnosis in itself. Pain is a key feature; other symptoms and signs may include sensory abnormalities (spontaneous burning pain and allodynia), autonomic dysfunction, trophic changes, impairment of motor function, and emotional/psychological responses.[4,73] The difference between CRPS types I and II is whether a nerve injury was involved (see Box 13.10).

Etiology of Symptoms

The underlying mechanism that stimulates the onset of these syndromes is unclear.[2,29] Symptoms usually develop in association with a persistent, painful lesion, such as a painful shoulder; after a cardiovascular accident or myocardial infarction; with cervical osteoarthritis; after trauma, such as a fracture or sprain; with burns or immobilization; or after surgery

BOX 13.10 Classification and Clinical Features of Complex Regional Pain Syndromes[64]

CRPS type I (reflex sympathetic dystrophy)
- Develops after an initiating noxious event
- Spontaneous pain or allodynia/hyperalgesia
- Edema, vascular abnormalities
- Abnormal sudomotor activity
- Non-nerve origin

CRPS type II (causalgia)
- Develops after nerve injury
- Not limited to territory of injured nerve
- Edema; skin blood flow abnormality
- Abnormal sudomotor activity

Clinical Features of CRPS (in addition to the differences listed above)
- Symptoms more marked distally in an extremity
- Symptoms progress in intensity and spread proximally
- Symptoms vary with time
- Disproportion of symptoms in relation to the causing event
- A specific diagnosis, such as diabetes or fibromyalgia, has been excluded

or cardiac catheterization.[2] There may or may not be an obvious nerve lesion.

The sympathetic nervous system is usually involved in CRPS type I (RSD); it is described as unstable owing to its continuous activity and leads to progressive ischemia, pain, abnormal pseudomotor activity, and trophic changes that are characteristically produced by dysfunction in the autonomic nervous system. Wasner and associates[76] demonstrated the origin of the autonomic dysfunction in one patient and two normal subjects to be in the central nervous system. Some individuals may have similar symptoms of intense burning pain and sensitivity suggestive of sympathetically maintained pain, yet are unresponsive to sympathetic blocks. The term "sympathetically independent pain" (SIP) is used to describe this sensory abnormality.[4,55] CPRS may be the result of various organic or psychiatric disorders that involve the nervous system.[50] No radiologic or laboratory tests reliably confirm or exclude this condition; medical diagnosis is based primarily on physical findings.[29]

Clinical Course

CRPS typically progresses through three stages.[1,29,37]

- **Stage I:** *Acute/reversible stage.* Typically, symptoms begin within several days after injury or insidiously over several weeks.[29] This stage of vasodilation lasts 3 weeks to 6 months. Pain, the predominant feature, is usually out of proportion to the severity of the injury. There is hyperhidrosis, warmth, erythema, rapid nail growth, and edema in the distal extremity (Fig. 13.22).

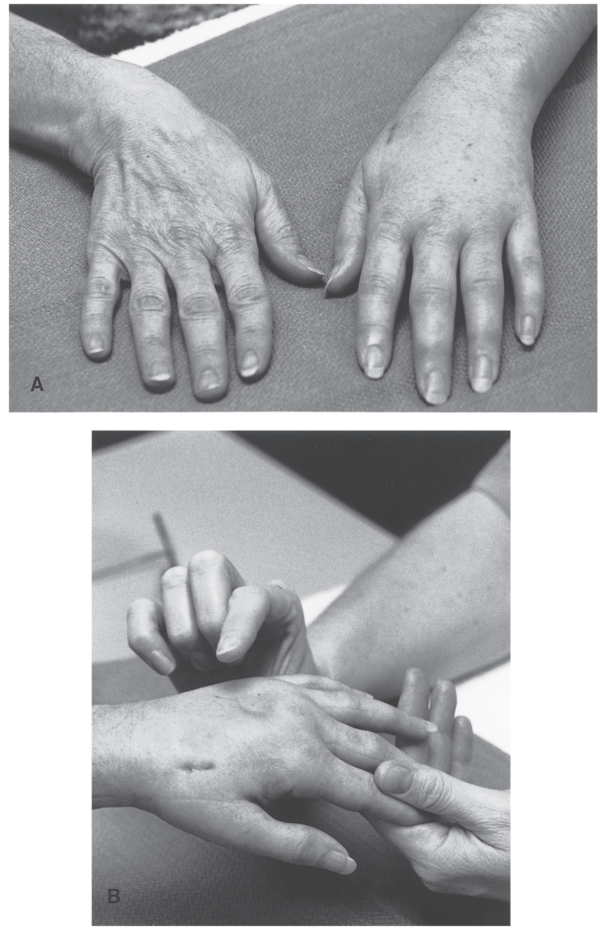

FIGURE 13.22 (A) In the early stages of reflex sympathetic dystrophy, generalized edema is present. This edema is often localized over the dorsum of the hand in the metacarpal and proximal interphalangeal joint areas. **(B)** The edema is usually of a pitting nature, as indicated by the indentation that remains once the pressure is removed.

CLINICAL TIP

It is important to recognize the early symptoms of CRPS, because early intervention may prevent progression.

- **Stage II:** *Dystrophic or vasoconstriction (ischemic) stage.* This stage typically begins around 3 months after the initial injury (although this varies) and lasts 3 to 6 months. It is characterized by sympathetic hyperactivity, burning pain, and hyperesthesia exacerbated by cold weather. There is mottling and coldness, brittle nails, and osteoporosis.
- **Stage III:** *Atrophic stage.* This begins 6 months to 1 year after injury, and is characterized by pain either decreasing or becoming worse and by severe osteoporosis. Muscle wasting and contractures may occur. The condition can last for months or years, but spontaneous recovery often occurs within 18 to 24 months.

Common Structural and Functional Impairments

- Pain or hyperesthesia in the extremity out of proportion to the injury.
- Limitation of motion. In the upper extremity, the shoulder typically develops limitation in a capsular pattern with most restriction in lateral rotation and abduction. In the wrist and hand, the most common restrictions are limited wrist extension and metacarpophalangeal and proximal interphalangeal flexion.
- Edema in the distal aspect of the extremity secondary to circulatory impairment of the venous and lymphatic systems, which in turn precipitates stiffness in the hand or foot.
- Vasomotor instability.
- Trophic changes in the skin.
- As the condition progresses, the pain subsides, but limitation of motion with increased fibrosis and synovial proliferation persists. The skin becomes cyanotic and shiny, and may be cool to touch. In the upper extremity, the intrinsic muscles of the hand atrophy; subcutaneous tissue in the fingers and palmar fascia thicken; nail changes occur; and osteoporosis develops. If the foot is involved, a fixed equinovarus may develop.[29]

Management

Intervention: Stage I (Box 13.10)

CRPS is a progressive disorder unless vigorous intervention is used during the acute stage.[75] The best intervention is prevention when it is recognized that development of this condition is a possibility, such as when there has been trauma to the extremity or when the extremity is immobilized. It requires that the therapist motivate the patient to move the entire extremity safely, minimize edema and vascular stasis with elevation and activity of the distal segments (squeeze and open hand with upper extremity lesions, or ankle pumping and toe curls with lower extremity lesions), and be alert to the development of adverse symptomatology.

BOX 13.11 Summary of Guidelines for Management of Complex Regional Pain Syndrome Type I (RSD)

Stage I (early intervention)

Relieve pain and control edema

- Modalities
- Retrograde massage
- Elevate, elastic compression

Increase mobility (specific to involved tissues)

- Tendon gliding in the hand
- Nerve mobilization

Improve muscle performance

- Stress loading in quadruped position
- Distraction

Improve total body circulation

- Low impact aerobic exercise

Desensitize the area

- Desensitization techniques for brief periods 5×/day

Educate the patient

- Teach interventions that deal with variable vasomotor responses; when to use heat, cold, gentle exercises

Stages II and III

Manage pain

- Modalities prior to or in conjunction with exercise

Desensitize the area

- Progress desensitization techniques to increase tolerance of various textures

Increase mobility (specific to involved tissues)

- Joint and soft tissue manipulation (with caution due to osteoporosis)
- Neuromobilizaiton
- Passive and self-stretching techniques

Improve functional performance

- Carefully monitor and progress strength, endurance, and functional exercises

Medical intervention is a necessity to manage this syndrome. The physician may choose to utilize analgesics, sympatholytic drugs, local anesthetic blocks, stellate ganglion blocks, spinal cord stimulation, or upper thoracic sympathectomy or may use oral steroids or intramuscular medication.[29,37] Because there is often an emotional or psychological component, medical intervention includes therapies to manage this area (antidepressants). This is done in conjunction with active exercise (including exercise in warm water) to manage physical impairments and functional limitations.

- ***Pain and edema control.*** Use modalities such as ultrasound, vibration, transcutaneous electrical nerve stimulation (TENS), or ice. Utilize retrograde massage. Elevate and use elastic compression when not undergoing pneumatic compression treatment.
- ***Mobility.*** In the early stages, use gentle, active exercises to manage the increasing stiffness.[38] Have the patient actively contract the musculature while the part is held near the end of the pain-free range. It is important to avoid increasing painful reactions that would decrease mobility. Support and have the patient actively move each joint for a short period of time. They should follow this program of brief motion frequently throughout the day.
  - In the hand, include tendon glide exercises (see Chapter 19, Fig. 19.17).
  - Butler[10] suggested that there may be adverse tension in the sympathetic trunk influencing sympathetic activity and therefore suggested mobilization of the nervous system, as described earlier in this chapter. Avoid vigorous stretching.
- ***Muscle performance.*** Facilitate active muscle contractions. Include joints proximal to the symptoms (shoulder/hip); they often develop restrictions due to pain or lack of use. Use both dynamic and isometric exercise and alternating controlled stress loading (compressive loading) with distraction activities for neuromuscular control as well as afferent fiber stimulation. The objective is to provide tissue stress with minimal joint motion. Suggested exercises include:[75,77]
  - Stress load the upper extremity by scrubbing with a brush in the quadruped position, beginning at 3 minutes and incrementally increasing to 10 minutes three times a day. For the lower extremity, utilize progressive weight-bearing activities.
  - Distraction by carrying 1 to 5 pounds up to 10 minutes at a time frequently throughout the day.
- ***Total body circulation and cardiac output.*** Initiate a program of low-impact aerobic exercises.
- ***Desensitization.*** Utilize desensitization techniques for brief periods five times per day, such as having the patient work with various textures and tap or vibrate over the sensitive area. Instruct the patient to wear a protective glove during activities of daily living (described earlier in the chapter).
- ***Patient education.*** Emphasize the importance of following the program of increased activity. Teach the patient interventions that deal with the variable vasomotor responses

with the use of gentle heat, gentle exercises for short periods throughout the day, and use of associated parts of the extremity.

CLINICAL TIP

It is important not to exacerbate the patient's pain and underlying pathology. If there is increased sensitivity, use caution when touching sensitive areas. Maintain continuous contact to avoid the irritation of "make-and-break" contact over the sensitive area, especially if utilizing massage for edema control.[75] When the patient presents with hypersensitivity, painful stretching or manipulations exacerbate the symptoms. Utilize gentle active exercises and light massage, for short periods, throughout the day.[38]

Intervention: Stages II and III

- ***Pain management.*** Modalities are often used as palliative interventions prior to or in conjunction with exercise to minimize pain.[75]
- ***Desensitization.*** Progress the desensitization techniques to increase the patient's tolerance to various textures.
- ***Mobility.*** Use joint mobilization, neuromobilization, and stretching techniques to address tissues limiting mobility. Use caution since osteoporosis is a frequent complication.

Because of the pain and significant limitations, there may be little progress with the stretching maneuvers, so surgical intervention may be required to gain motion.[68]

- ***Muscle performance.*** Develop an exercise program to improve strength, endurance, and overall functional performance that meets the specific needs of the patient.

CLINICAL TIP

Pain continues to be a variable during stages II and III, and therefore, the initiation of any therapeutic exercise or manual therapy technique should be carefully monitored and adapted to the patient at each visit to minimize exacerbation of symptoms.[75]

FOCUS ON EVIDENCE

Evidence supports effective use of physical therapy with early intervention (acute stage), but there is contradictory evidence for its effectiveness during the later stages.[28,32] In one study, the primary predictors for success and satisfaction with patients during the chronic phase after 6 months of therapy (evaluated at 12 months) was with the patient group that began therapy at a higher baseline of function, higher baseline ROM and strength, and less baseline pain.[32]

Independent Learning Activities

Critical Thinking and Discussion

1. Your patient describes intermittent sensory changes in the index and middle finger. What are the possible causes? What tests would you use to examine this patient? What results would lead you to determine nerve mobility restrictions?
2. You have a new client who describes intermittent tingling and sensations of heaviness in his hands whenever working with his hands in an overhead position. He is an auto mechanic and frequently has to work this way. Identify possible causes of these symptoms. What is usually the source of "tingling" sensations? What may be the source of the "heaviness" feelings? Why would the overhead position cause both vascular and neurological symptoms? Identify possible sites that could cause these symptoms. What tests would you use to confirm or rule out your hypotheses?
3. A 19-year-old patient presents with the medical diagnosis of complex regional pain syndrome type I (RSD) and the following history.[52]
   - Three-month history of midfoot pain that increases with standing more than 5 minutes or running. Symptoms have increased over the past 3 weeks.
   - Stress fracture to the navicular was detected on radiography, so patient was placed in a BK nonweight-bearing cast.
   - Foot discomfort increased and became more diffuse, radiating into the lateral forefoot and digits even after pain medications were prescribed.
   - Symptoms increased with burning or stinging pain, edema, and discoloration of the digits.
   - Examination 3 weeks after cast applied: digits cool, edematous, hyperesthetic, and hyperhidrotic. Passive and active motions of ankle and toes were moderately painful. Radiographs showed diffuse osteoporosis.

   What would be your goals for this patient? Develop a program of interventions.
4. Identify and describe everyday activities and/or positions that mimic the nerve tension test positions. These activities/positions may be patient complaints that indicate further nerve tension testing. For example, getting into a car by straightening the leg and ducking the head mimics the "slump" position.

Laboratory Practice

1. With your laboratory partner, practice each of the nerve tension positions. Demonstrate how you would mobilize restrictions for each of the nerves.

2. Practice each of the thoracic outlet tests and describe the mechanics of each test. Identify and practice techniques you could use to increase mobility or reduce compression on the brachial plexus at each of the sites where compression or tension might occur. Design an exercise program and progression for managing impairments that could cause TOS symptoms.
3. Practice sensory stimulation and reintegration techniques by doing each of the following.
   - Gather 10 pieces of material of various textures. Place them in order of least irritating to most irritating. Practice sensory stimulation techniques by gently rubbing each material across your fingers.
   - Use five plastic tubs or buckets. Place each of the following in a container: dry peas or beans, spiral macaroni, sand, fine gravel, seeds. Practice sensory stimulation by moving your hand (or foot) through each of the textures.
   - Have your laboratory partner place several familiar household items in a bag (e.g., key, dime, penny, can opener). Without looking, attempt to identify each one.

IV Exercise Interventions by Body Region

CHAPTER

14

The Spine: Structure, Function, and Posture

Posture is alignment of the body parts whether upright, sitting, or recumbent. It is described by the positions of the joints and body segments and also in terms of the balance between the muscles crossing the joints.[41] Impairments in the joints, muscles, or connective tissues may lead to faulty postures; or, conversely, faulty postures may lead to impairments in the joints, muscles, and connective tissues as well as symptoms of discomfort and pain. Many musculoskeletal complaints can be attributed to stresses that occur from repetitive or sustained activities when in a habitually faulty postural alignment. This chapter reviews the structural relationships of the spine and extremities to normal and abnormal posture and describes the mechanisms that control posture. Common postural impairments and general guidelines for their management are described. Specific exercises for the various body regions are highlighted in this chapter and are described in detail in the succeeding chapters in Part IV of the text. Chapter 15 describes the common pathologies associated with the spine and details management guidelines, and Chapter 16 describes spinal exercises and manual interventions in detail.

Structure and Function of the Spine

Structure

The structure of the spinal column consists of 33 vertebrae (7 cervical, 12 thoracic, 5 lumbar, 5 fused sacral, and 3 or 4 coccygeal) and their respective intervertebral discs. Articulating with the spine are the 12 pair of ribs in the thoracic region, the cranium at the top of the spine at the occipital-atlas joint, and the pelvis at sacroiliac joint (Fig. 14.1).

Functional Components of the Spine

Functionally, the spinal column is divided into anterior and posterior pillars (Fig. 14.2).[14]

- The *anterior pillar* is made up of the vertebral bodies and intervertebral discs and is the hydraulic, weight-bearing,

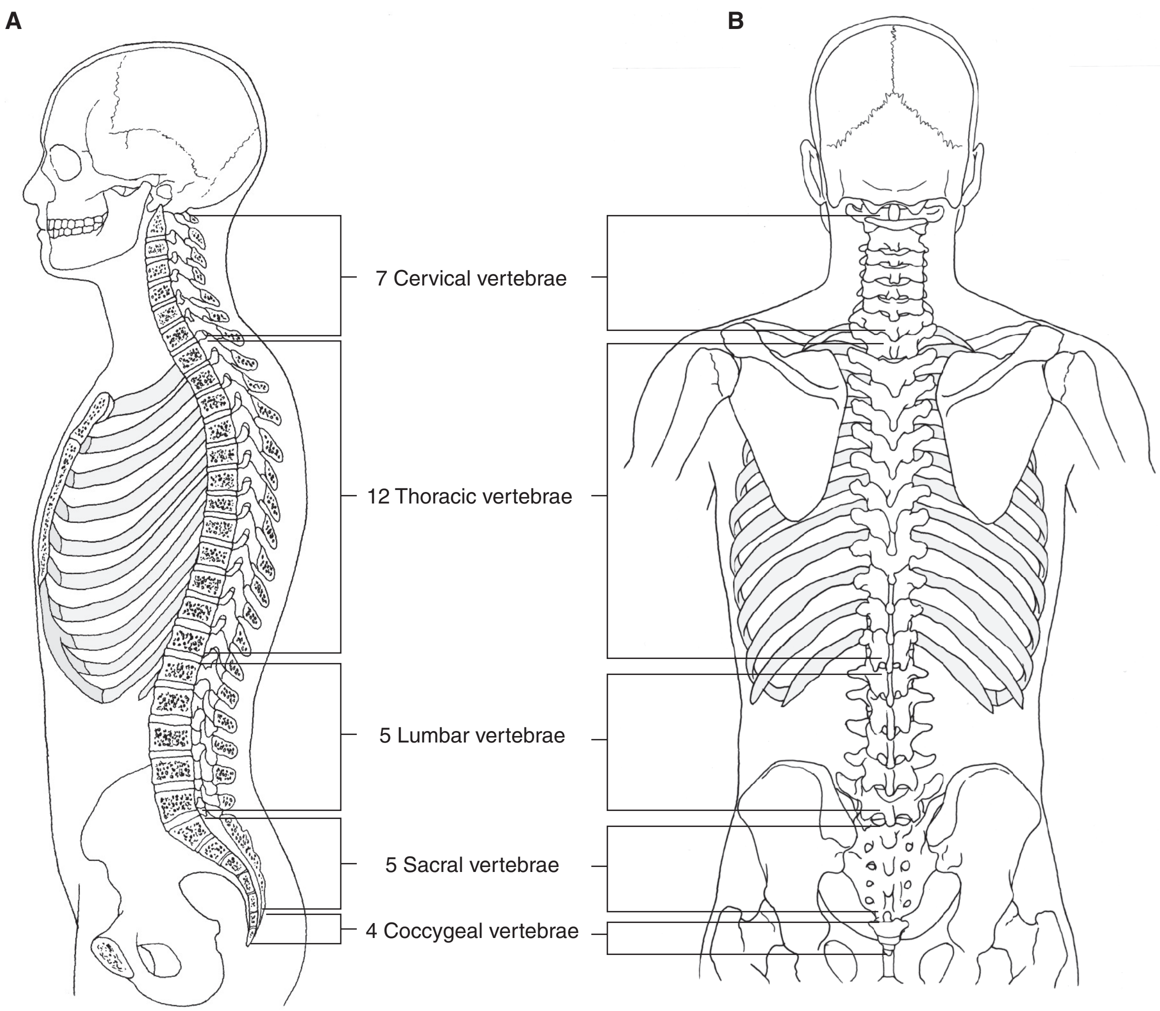

FIGURE 14.1 (A) Lateral and **(B)** posterior views showing the five regions of the spinal column. *(From Levangie and Norkin,[14] p. 141 with permission.)*

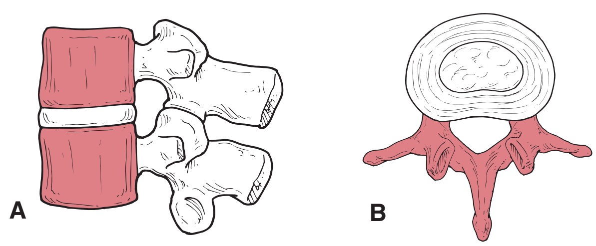

FIGURE 14.2 Spinal segment showing **(A)** the anterior weight-bearing, shock-absorbing portion, and **(B)** the posterior gliding mechanism and lever system for muscle attachments.

shock-absorbing portion of the spinal column. The size of the disc influences the amount of motion available between two vertebrae.[14]

- The *posterior pillar*, or vertebral arch, is made up of the articular processes and facet joints, which provide the gliding mechanism for movement. The orientation of the facets influences the direction of motion.[14] Also part of the posterior unit are the boney levers, the two transverse processes, and the spinous process to which the muscles attach and function to cause and control motions and provide spinal stability.

Motions of the Spinal Column

Motion of the spinal column is described both globally and at the functional unit or motion segment. The functional unit is comprised of two vertebrae and the joints in between (typically, two zygapophyseal facet joints and one intervertebral disc). Generally, the axis of motion for each unit is in the nucleus pulposus of the intervertebral disc. Because the spine can move from top down or bottom up, motion at a functional unit is defined by what is occurring with the anterior portion of the body of the superior vertebra (Fig. 14.3).

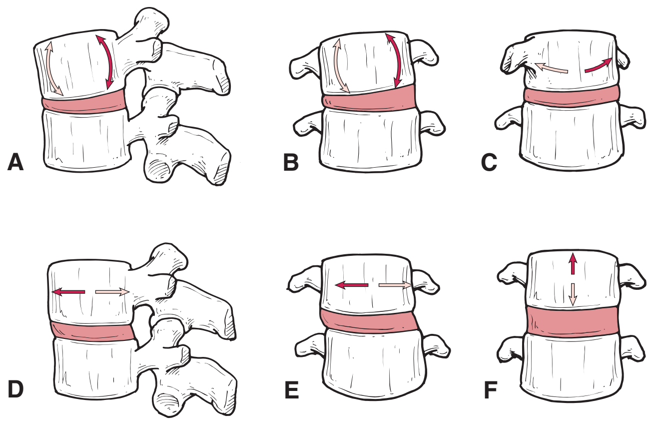

FIGURE 14.3 Motions of the spinal column. (A) Flexion/extension (forward/backward bending). (B) Lateral flexion (side bending). (C) Rotation. (D) Anterior/posterior shear. (E) Lateral shear. (F) Distraction/compression.

The Six Degrees of Motion

Flexion/Extension. Motion in the sagittal plane results in flexion (forward bending) or extension (backward bending). With flexion, the anterior portion of the bodies approximate and the spinous processes separate; with extension, the anterior portion of the bodies separate and the spinous processes approximate.

Side bending. Motion in the frontal plane results in side bending (lateral flexion) to the left or right. With side bending, the lateral edges of the vertebral bodies approximate on the side toward which the spine is bending and separate the opposite side.

Rotation. Motion in the transverse plane results in rotation. Rotation to the right results in relative movement of the body of the superior vertebrae to the right and its spinous process to the left; the opposite occurs with rotation to the left. If movement occurs from the pelvis upward, the motion is still defined by the relative motion of the top vertebra.

Anterior/posterior shear. Forward or backward shear (translation) occurs when the body of the superior vertebra translates forward or backward on the vertebra below.

Lateral shear. Lateral shear (translation) occurs when the body of the superior vertebra translates sideways on the vertebra below.

Compression/distraction. Separation or approximation occurs with a longitudinal force, either away from or toward the vertebral bodies.

Arthrokinematics of the Zygapophyseal (Facet) Joints

Each region of the spine has its own special considerations as pertains to arthrokinematic movement and function. The arthrokinematics of the craniovertebral (suboccipital) area are described below. The remainder of the cervical spine and all the thoracic facets have relatively flat articular surfaces and glide on the adjacent facet joint.[14] The superior facets of the lumbar spine are concave and articulate with the adjacent inferior convex facets.[59] The arthrokinematics are summarized in Table 14.1.

Coupled motions typically occur at a segmental level when a person side bends or rotates their spine. *Coupled motion* is defined as "consistent association of one motion about an axis with another motion around a different axis"[14] and varies depending on the region, the spinal posture, the orientation of the facets, and factors such as extensibility of the soft tissues. When motions of side bending and rotation are coupled, foraminal opening is dictated by the side bending component.

Cervical spine. The cervical spine can be divided into the suboccipital (craniovertebral) region and the "typical" cervical region.

- The *suboccipital region* is composed of the occiput, atlas, and superior facets of the axis.
  - The occipital-atlantal (OA) joint is considered a ball and socket joint; the convex facets of the occiput articulate with the concave facets of the atlas. Its primary motions are forward and backward nodding (flexion and extension) (Fig. 14.4).
  - The atlantal-axial (AA) joint consists of convex articulating surfaces of the atlas articulating on the convex articulating surfaces of the axis; its primary motion is rotation as the atlas pivots around the dens of the axis. It is important to note that, during rotation, one side of the AA joint complex is behaving as though it is flexing (moving forward) and the other side as though it is extending (moving backward) (Fig. 14.5). There is a small amount of side bending available at the OA joint; rotation and side bending are coupled in opposite directions in this region.
- The *typical cervical* region includes the inferior facets of the axis and rest of the cervical spine; it features facet joints that are angled at 45° from the horizontal plane. Side bending and rotation typically couple toward the same side.
- Another unique characteristic of the cervical spine is the *joints of Luschka*. These boney projections provide lateral stability to the spine and reinforce the vertebral disc posterolaterally.

Thoracic spine. The thoracic facets begin in a frontal plane orientation and transition to a sagittal plane orientation as they near the lumbar spine. The ribs articulate with the thoracic spine at the transverse processes as well as the vertebral bodies and IV discs. In the upright posture, side bending and rotation typically couple in the same direction in the upper thoracic spine and in the opposite directions in the lower thoracic region,[14] although variability has been described.[70]

TABLE 14. 1 Arthrokinematics of the Spine

Spinal Area	Joint Motion	Facet Motion of Superior Vertebrae	Foraminal Size
Suboccipital region: occiput/atlas (O/A) and atlas/axis (A/A)	Flexion	The condyles of the occiput roll anterior and slide posterior; atlas slides forward on the axis	Minimal change
	Extension	The condyles of the occiput roll posterior and slide anterior; atlas slides posterior on the axis	Minimal change
	Rotation	Ipsilateral facet of atlas goes posterior and contralateral facet goes anterior	Ipsilateral opening, contralateral closing
	Side bending	Slight amount at O/A: ipsilateral condyle of occiput slides medial, contralateral condyle slides lateral	Minimal change
Typical cervical, thoracic, and lumbar regions	Flexion	Inferior facets slide upward	Bilateral opening
	Extension	Inferior facets slide downward	Bilateral approximation
	Rotation	Ipsilateral facets slide downward, contralateral facets slide upward	Ipsilateral separation; contralateral approximation
	Side bending	Ipsilateral facets slide downward, contralateral facets slide upward	Ipsilateral approximation; contralateral separation Note: when side bending and rotation are coupled, foraminal opening is dictated by the side bending component
Sacrum	Flexion	Occurs with lumbar extension	NA
	Extension	Occurs with lumbar flexion	NA
	Rotation	Occurs with lumbar rotation in the contralateral direction	NA
	Side bending	Occurs with lumbar side bending in the contralateral direction	NA

Lumbar spine. As the lumbar facets transition from a sagittal plane to a frontal plane orientation, some of the facets have a biplanar orientation.[14] Coupling varies in that with lateral flexion, rotation occurs to the same side, but with rotation, lateral flexion occurs opposite[14]; there is variability with flexion and extension.

Structure and Function of Intervertebral Discs

The intervertebral disc, consisting of the annulus fibrosus and nucleus pulposus, is one component of a three-joint complex between two adjacent vertebrae. The structure of the disc dictates its function (Fig. 14.6).[14,45]

Annulus fibrosus. The outer portion of the disc is made up of dense layers of collagen fibers and fibrocartilage. The collagen fibers in any one layer are parallel and angled around 60° to 65° to the axis of the spine, with the tilt alternating in successive layers.[26,42] Because of the orientation of the fibers, tensile strength is provided to the disc by the annulus when the spine is distracted, rotated, or bent. This structure helps restrain the various spinal motions as a complex ligament. The annulus is firmly attached to adjacent vertebrae, and the layers are firmly bound to one another. Fibers of the innermost layers blend with the matrix of the nucleus pulposus. The annulus fibrosus is supported by the anterior and posterior longitudinal ligaments.

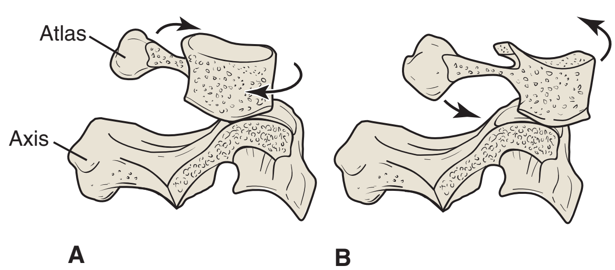

FIGURE 14.5 Rotation of the atlas-axis joints (view from the side). **(A)** Right rotation showing backward movement of the right articulating surface of C1 on C2. **(B)** Left rotation showing forward movement of the right articulating surface of C1 on C2.

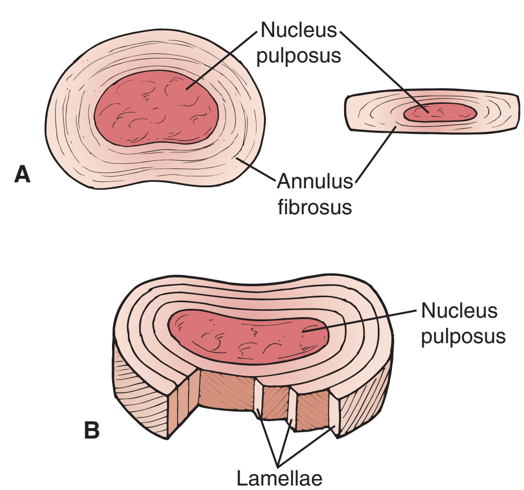

FIGURE 14.6 Intervertebral disc. **(A)** The annular rings enclose the nucleus pulposus, providing a mechanism for dissipating compressive forces. **(B)** Orientation of the layers of the annulus provides tensile strength to the disc with motions in various directions.

Nucleus pulposus. The central portion of the disc is a gelatinous mass that normally is contained within, but whose loosely aligned fibers merge with the inner layer of the annulus fibrosus. It is located centrally in the disc except in the lumbar spine, where it is situated closer to the

posterior border than the anterior border of the annulus. Aggregating proteoglycans, normally in high concentration in a healthy nucleus, have great affinity for water. The resulting fluid mechanics of the confined nucleus functions to distribute pressure evenly throughout the disc and from one vertebral body to the next under loaded conditions. Because of the affinity for water, the nucleus imbibes water when pressure is reduced on the disc and squeezes water out under compressive loads. These fluid dynamics provide transport for nutrients and help maintain tissue health in the disc.

With flexion (forward bending) of a vertebral segment, the anterior portion of the disc is compressed, and the posterior is distracted. The nucleus pulposus generally does not move in a healthy disc but may have slight distortion with flexion, potentially to redistribute the load through the disc.[43] Asymmetrical loading in flexion results in distortions of the nucleus toward the contralateral posterolateral corner, where the fibers of the annulus are more stretched.

Cartilaginous end-plates. End-plates cover the nucleus pulposus superiorly and inferiorly and lie between the nucleus and vertebral bodies. Each is encircled by the apophyseal ring of the respective vertebral body.[14] The collagen fibers of the inner annulus fibrosus insert into the end-plate and angle centrally, thus encapsulating the nucleus pulposus. Nutrition diffuses from the marrow of the vertebral bodies to the disc via the end-plates.[14] The end-plates are also responsible for containing the nucleus from migrating superior/inferior.

Intervertebral Foramina

The intervertebral foramina are between each vertebral segment in the posterior pillar. Their anterior boundary is the intervertebral disc; the posterior boundary is the facet joint; and the superior and inferior boundaries are the pedicles of the superior and inferior vertebrae of the spinal segment. The mixed spinal nerve exits the spinal canal via the foramen along with blood vessels and recurrent meningeal or sinuvertebral nerves. The size of the intervertebral foramina is affected by spinal motion, being larger with forward bending and contralateral side bending and smaller with extension and ipsilateral side bending.

Biomechanical Influences on Postural Alignment

Curves of the Spine

The adult spine is divided into four curves: two *primary*, or posterior, curves, so named because they are present in the infant and the convexity is posterior; and two *compensatory*, or anterior, curves, so named because they develop as the infant learns to lift the head and eventually stand, and the convexity is anterior.

- Posterior curves are in the thoracic and sacral regions. *Kyphosis* is a term used to denote a posterior curve. Kyphotic posture refers to an excessive posterior curvature of the thoracic spine.[41]
- Anterior curves are in the cervical and lumbar regions. *Lordosis* is a term also used to denote an anterior curve, although some sources reserve the term lordosis to denote abnormal conditions such as those that occur with a sway back.[41]
- The curves and flexibility in the spinal column are important for withstanding the effects of gravity and other external forces.[14,51]
- The structure of the bones, joints, muscles, and inert tissues of the lower extremities are designed for weight bearing; they support and balance the trunk in the upright posture. Lower extremity alignment and function are described in greater detail in each of the extremity chapters (see Chapters 20 to 22).

Gravity

When looking at posture and function, it is critical to understand the influence of gravity on the structures of the trunk and lower extremities. Gravity places stress on the structures responsible for maintaining the body upright and therefore, provides a continual challenge to stability and efficient movement. For a weight-bearing joint to be stable, or in equilibrium, the gravity line of the mass must fall exactly through the axis of rotation, or there must be a force to counteract the moment caused by gravity.[44] In the body, the counterforce is provided by either muscle or inert structures. In addition, the standing posture usually involves a slight anterior/posterior swaying of the body of about 4 cm., so muscles are necessary to control the sway and maintain equilibrium.

In the upright posture, the line of gravity transects the spinal curves, which are balanced anteriorly and posteriorly, and it is close to the axis of rotation in the lower extremity joints. The following describes the standard of a balanced upright posture (Fig. 14.7).

Ankle. For the ankle, the gravity line is anterior to the joint, so it tends to rotate the tibia forward about the ankle. Stability is provided by the plantarflexor muscles, primarily the soleus muscle.

Knee. The normal gravity line is anterior to the knee joint, which tends to keep the knee in extension. Stability is provided by the anterior cruciate ligament, posterior capsule (locking mechanism of the knee), and tension in the muscles posterior to the knee (the gastrocnemius and hamstring muscles). The soleus provides active stability by pulling posteriorly on the tibia. With the knees fully extended, no muscle support is required at that joint to maintain an upright

FIGURE 14.7 Lateral view of standard postural alignment. A plumb line is typically used for reference and represents the relationship of the body parts with the line of gravity. Surface landmarks are slightly anterior to the lateral malleolus, slightly anterior to the axis of the knee joint, through the greater trochanter (slightly posterior to the axis of the hip joint), through the bodies of the lumbar and cervical vertebrae, through the shoulder joint, and through the lobe of the ear.

posture; however, if the knees flex slightly, the gravity line shifts posterior to the joint, and the quadriceps femoris muscle must contract to prevent the knee from buckling.

Hip. The gravity line at the hip varies with the swaying of the body. When the line passes through the hip joint, there is equilibrium, and no external support is necessary. When the gravitational line shifts posterior to the joint, some posterior rotation of the pelvis occurs, but is controlled by tension in the hip flexor muscles (primarily the iliopsoas). During relaxed standing, the iliofemoral ligament provides passive stability to the joint, and no muscle tension is necessary. When the gravitational line shifts anteriorly, stability is provided by active support of the hip extensor muscles.

Trunk. Normally, the gravity line in the trunk goes through the bodies of the lumbar and cervical vertebrae, and the curves are balanced. Some activity in the muscles of the trunk and pelvis helps maintain the balance. (This is described in greater detail in the following sections.) As the trunk shifts, contralateral muscles contract and function as guy wires. Extreme or sustained deviations are supported by inert structures.

Head. The center of gravity of the head falls anterior to the atlanto-occipital joints. The posterior cervical muscles contract to keep the head balanced.

Stability

So long as the line of gravity from the center of mass falls within the base of support, a structure is stable. Stability is improved by lowering the center of gravity or increasing the base of support. In the upright position, the body is relatively unstable, because it is a tall structure with a small base of support. When the center of gravity falls outside the base of support, either the structure falls or some force must act to keep the structure upright. Both inert and dynamic structures support the body against gravitational and other external forces. The inert osseous and ligamentous structures provide passive tension when a joint reaches the end of its range of motion (ROM). Muscles act as dynamic guy wires, responding to perturbations by providing counterforces to the torque of gravity as well as stability within the ROM so stresses are not placed on the inert tissues.

Postural Stability in the Spine

Spinal stability is described in terms of three subsystems: passive (inert structures/bones and ligaments), active (muscles), and neural control.[19,58] The three subsystems are interrelated and can be thought of as a three-legged stool; if any one of the legs is not providing support, it affects the stability of the whole structure.[58] Instability of a spinal segment is often a combination of inert tissue damage, insufficient muscular strength or endurance, and poor neuromuscular control.[3,19]

Inert Structures: Influence on Stability

Penjabi[57,58] described the ROM of any one segment as being divided into an elastic zone and a neutral zone. When spinal segments are in the neutral zone (midrange/neutral range), the inert joint capsules and ligaments provide minimal passive resistance to motion and therefore, minimal stability. As a segment moves into the elastic zone, the inert structures provide restraint as passive resistance to the motion occurs. When a structure limits movement in a specific direction, it provides stability in that direction. In addition to the inert tissues providing passive stability when limiting motion, the sensory receptors in the joint capsules and ligaments sense position and changes in position. Stimulation of these receptors provides feedback to the central nervous system, thus influencing the neural control system.[58,60] Table 14.2 summarizes the stabilizing features of the osteoligamentous tissues in the spine.

TABLE 14.2 Stabilizing Features of Inert Tissues in the Spine

Structure	Feature	Limits
Facet joint orientation		
Cervical spine facets oriented in frontal plane with oblique angulation toward transverse plane	Allows free forward bending (flexion) and backward bending (extension)	Capsule taut at end of flexion; joint surfaces approximate at end of extension
Thoracic spine facets: upper spine similar to cervical, mid to lower facets more in sagittal plane	Rotation, side bending, and forward bending are allowed to various degrees by the facets	Facets are not as restricting as ribs and spinous processes
Lumbar spine facets in sagittal plane with some curvature in frontal plane[8]	Forward and backward bending allowed	Restricts rotation; frontal plane orientation provides stability at end of range in flexion[67]
Ribs		
	Ribs approximate on side of spinal concavity with any motion	Restricts forward bending, side bending, and rotation in the thoracic region
Spinous processes		
	Spinous processes approximate with extension; the longer the process the greater the restriction	Restricts extension, especially in the thoracic region; may approximate in lumbar region with flexible individual
Intervertebral discs		
	Greater the ratio of disc thickness to vertebral height the greater the mobility	Cervical spine (ratio 2:5) most mobile Lumbar spine (ratio 1:3) Thoracic spine (ratio 1:5) least mobile
Annulus fibrosus	Organized concentric rings behave similar to ligaments[8]	Some fibers are taut whichever direction the spinal segment rotates or sheers[42] Fibers slack on side of concavity and taut on side of convexity
Ligaments		
	Slack midrange, taut at end of range	Forward bending limited by the interspinous and supraspinous ligaments, capsular ligaments, ligamentum flavum, and posterior longitudinal ligament. Backward bending limited by the anterior longitudinal ligament Side bending limited by the contralateral intertransverse ligaments, ligamentum flavum, and capsular ligaments Rotation limited by the capsular ligaments
Thoracolumbar (lumbodorsal) fascia		
	Extensive fascial system consists of several layers surrounding erector spinae and quadratus lumborum; has static and dynamic function	Limits end-range of forward bending of the lumbar spine (See also dynamic stabilizing function)
Muscles		
	Muscles with normal elasticity do not cause limitations of spinal movement; normally provide dynamic stability and control	When muscles develop contractures, they restrict movement opposite to their direction of contraction

Muscles: Influence on Stability

Role of Global and Segmental Muscle Activity

The muscles of the trunk not only act as prime movers or as antagonists to movement caused by gravity during dynamic activity, they are important stabilizers of the spine.[3,8,9,22,34,49,60] Without the dynamic stabilizing activity from the trunk muscles, the spine would collapse in the upright position.[12] Both superficial (global) and deep (segmental) muscles play critical roles in providing stability and maintaining the upright posture. Table 14.3 summarizes the stabilizing characteristics of these two muscle groups.

Global muscle function. In the lumbar spine, the global muscles, being the more superficial of the two groups, are the large guy wires that respond to external loads imposed on the trunk that shift the center of mass (Fig. 14.8 A). Their reaction is direction-specific to control spinal orientation.[3,34] The global muscles are unable to stabilize individual spinal segments except through compressive loading, because they have little or no direct attachment to the vertebrae. If an individual segment is unstable, compressive loading from the global guy wires may lead to or perpetuate a painful situation as stress is placed on the inert tissues at the end of the range of that segment (Fig. 14.8 B).

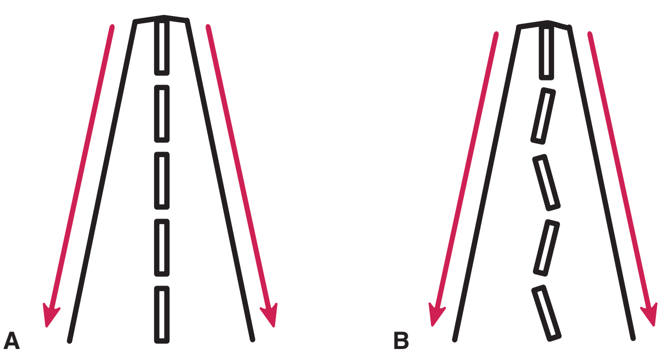

FIGURE 14.8 (A) Guy wire function of global trunk muscles provides overall stability against perturbations. **(B)** Instability in the multisegmental spine cannot be controlled by the global trunk muscle guy wires. Compressive loading from the long guy wires leads to stress on the inert tissues at the end-ranges of the unstable segment.

Deep/segmental muscle function. The deeper, segmental muscles, which have direct attachments across the vertebral segments, provide dynamic support to individual segments in the spine and help maintain each segment in a stable position, so the inert tissues are not stressed at the limits of motion (Fig. 14.9).[34,38,39,50]

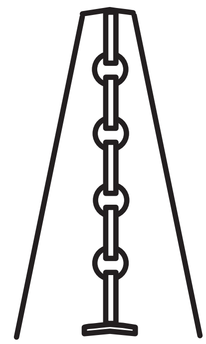

FIGURE 14.9 Deep muscles attached to each spinal segment provide segmental stability.

TABLE 14.3 Stabilizing Features of Muscles Controlling the Spine

Global Muscles	Deep Segmental Muscles
Characteristics	
■ Superficial: farther from axis of motion	■ Deep: closer to axis of motion
■ Cross multiple vertebral segments	■ Attach to each vertebral segment
■ Produce motion and provide large guy wire function	■ Control segmental motion; segmental guy wire function
■ Compressive loading with strong contractions	■ Greater percentage of type I muscle fibers for muscular endurance
Lumbar region	
■ Rectus abdominis	■ Transversus abdominis
■ External and internal obliques	■ Multifidus
■ Quadratus lumborum (lateral portion)	■ Quadratus lumborum (deep portion)
■ Erector spinae	■ Deep rotators
■ Iliopsoas	
Cervical region	
■ Sternocleidomastoid	■ Rectus capitis anterior and lateralis
■ Scalene	■ Longus colli
■ Levator scapulae	
■ Upper trapezius	
■ Erector spinae	

Muscle Control in the Lumbar Spine

General muscle function and stabilizing actions of the muscles of the spine are summarized in Table 14.4.

TABLE 14.4 Muscles of the Spine and Their Stabilizing Function

Muscles	Prime Action	Stabilizing Function
Lumbar spine		
Rectus abdominis (RA)	Trunk flexion (sit-up and curl-up exercises)[48]	▪ Stabilizes pelvis against anterior rotation forces[62] ▪ Provides long guy wire stability with backward bending (extension) loads on the spine
Internal obliques (IO) and external obliques (EO)	Bilateral contraction causes trunk flexion; EO on one side with IO on contralateral side together cause diagonal trunk rotation with flexion; EO and IO on same side cause side bending of trunk	▪ Controls against external loads that would cause backward bending or side bending of the spine ▪ Stabilizes pelvis (along with rectus abdominis) against anterior rotation forces ▪ Contracts in bracing maneuver to stiffen spine; increases compressive load ▪ Contracts with transverses abdominis to increase intra-abdominal pressure and place tension on thoracolumbar fascia to stabilize[11]
Transversus abdominis (TrA)	Contributes to rotation[11]	▪ Creates tension via thoracolumbar fascia and increases intra-abdominal pressure to provide segmental stability ▪ Activates with “drawing-in” maneuver for segmental stability[61,68]
Quadratus lumborum (QL)	Pelvic hiking and side bending of the spine	▪ Provides frontal and sagittal plane stability[48] ▪ Stabilizes ribs against pull of the diaphragm during inspiration[4] ▪ Deep fibers provide segmental stability to lumbar vertebrae
Multifidus	Spinal extension and contralateral rotation	▪ Stabilizes spine against flexion and rotation moments and contralateral side flexion moments ▪ Deep fibers provide segmental stability to lumbar vertebrae ▪ Activated with the “drawing in” and bracing maneuvers for spinal stabilization[61]
Intersegmental rotators and intertransversarii	These muscles are rich in muscle spindles and may function to sense vertebral position and motion more so than to produce torque for movement	▪ Theoretically, these muscles are in position to make small segmental adjustments to stabilize against perturbations to posture
Superficial erector spinae (ES) muscles (iliocostalis, longissimus, spinalis)	Primary trunk extensors; extend thorax on pelvis causing spinal backward bending; also side bending and posterior translation of the vertebrae	▪ Antagonist to gravity—control movement of trunk during forward bending activities ▪ Long guy wires that provide global stability to the trunk by responding to external loads and preventing the trunk from falling over

Muscles	Prime Action	Stabilizing Function
Iliopsoas (iliacus and psoas major)	Primary hip flexors and indirectly lumbar extensors; Iliopsoas creates an anterior shear on the lumbar vertebrae	■ This muscle complex does not function as a spinal stabilizer in normal standing.[2,48] ■ Iliacus stabilizes the pelvis and hip joints and thus indirectly influences spinal posture ■ Psoas assists in stabilizing the lumbar spine in the frontal plane, especially when a heavy load is applied to the contralateral side[2]
Cervical spine		
Sternocleidomastoid and scalene group	Bilateral contraction causes cervical flexion; unilateral contraction causes side bending with contralateral rotation and flexion When the neck is stabilized, the scalenes elevate the upper ribs during inspiration, and the sternocleidomastoids (SCM) elevate the clavicles and sternum, which assists in inspiration	■ Balance the head on the thorax against the forces of gravity when the center of mass is posterior
Upper trapezius and cervical erector spinae	Bilateral contraction causes cervical and capital extension; unilateral contraction causes side bending	■ Balance the head on the thorax against the forces of gravity when the center of mass is anterior
Levator scapulae	The levator scapulae works with the upper trapezius to elevate the scapulae	■ Supports the posture of the scapulae
Longus colli; rectus capitis anterior and lateralis	Craniocervical flexors; longus colli is the prime mover for cervical retraction (axial extension)	■ Provides segmental stability to cervical spine

Abdominal muscles (Fig. 14.10). The rectus abdominis (RA), external oblique (EO), and internal oblique (IO) muscles are large, multisegmental global muscles and are important guy wires for stabilizing the spine against postural perturbations. The transversus abdominis (TrA) is the deepest of the abdominal muscles and responds uniquely to postural perturbations. It attaches posteriorly to the lumbar vertebrae via the posterior and middle layers of the thoracolumbar fascia (Figs. 14.11 and 14.12) and through its action develops tension that acts like a girdle of support around the abdomen and lumbar vertebrae. Only the TrA is active with both isometric trunk flexion and extension, whereas the other abdominal muscles have decreased activity with resisted extension. This is attributed to the stabilization function of the TrA.[11,36]

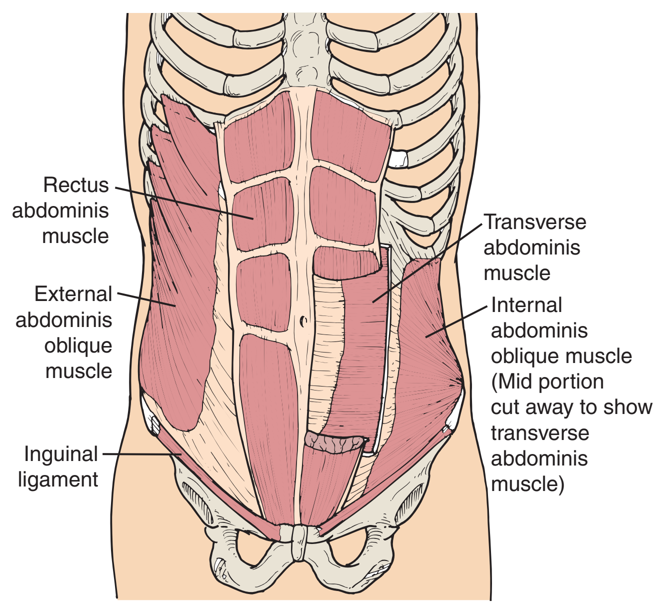

FIGURE 14.10 Abdominal muscles.

Transversus abdominis stabilization activity. Early electromyographic research studies of the activity of the deeper abdominal muscles in their stabilization function were done with surface electrodes and did not discriminate activity between the TrA and IO. By using ultrasound imaging techniques,

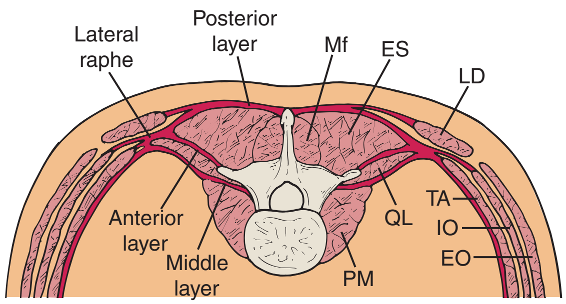

FIGURE 14.11 Transverse section in the lumbar region shows the relationships of the three layers of the thoracolumbar fascia to the muscles in the region and their attachments to the spine. (ES, erector spinae; Mf, multifidus; TA, transversus abdominis; IO, internal obliques; EO, external obliques; LD, latissimus dorsi; PM, psoas major; QL, quadratus lumborum muscles.)

insertion of fine-needle electrodes into the various muscles has produced evidence of differing functions between these two muscles with perturbations to balance in healthy individuals as well as those who have low back pathology.[32]

The TrA responds with anticipatory activity and with rapid arm and leg movements (before the other abdominals) and coordinates with respiration during these activities.[34,38,39] The TrA also has a coordinated link with the perineum and pelvic floor muscle function (see Chapter 24),[6,13,52,63,64] as well as with the deep fibers of the multifidi.[34,37-39,50] The "drawing-in" maneuver is used to activate the TrA voluntarily and, with training, produces the most independent activity of this muscle.[61,68] (See Chapter 16 for a description of this maneuver.)

FOCUS ON EVIDENCE

It has been shown that activation and function in the TrA change (delayed and more phasic) in patients with low back pain, possibly indicating less effective stabilizing action[32,35] and that training the TrA for postural control and stability improves the long-term outcome.[27]

Erector spinae muscles (Fig. 14.13). The erector spinae muscles are the long, multisegmental extensors that begin as a large musculotendinous mass over the sacral and lower lumbar vertebrae. They are important global guy wires for controlling the trunk against postural perturbations.

Multifidus stabilization activity. The multifasciculed multifidi muscle group has a high distribution of type I fibers and large capillary network, emphasizing its role as a tonic stabilizer. Its segmental attachments are able to control movement of the spinal segments as well as increase spinal stiffness. The

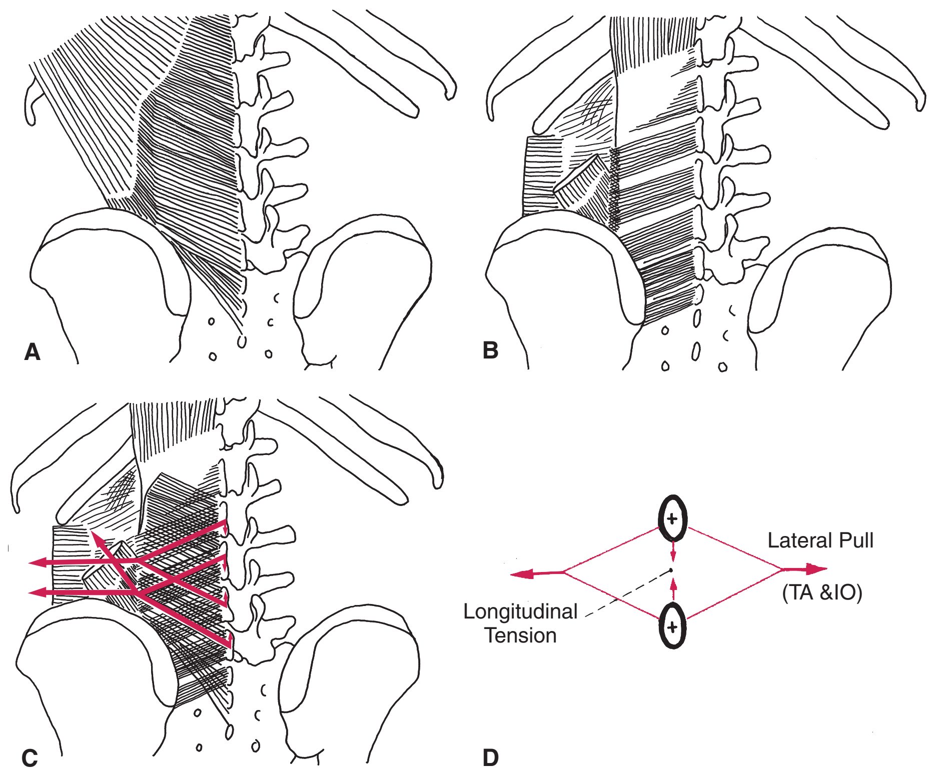

FIGURE 14.12 Orientation and attachments of the posterior layer of the thoracolumbar fascia. From the lateral raphe, **(A)** the fibers of the superficial lamina are angled inferiorly and medially and **(B)** the fibers of the deep lamina are angled superiorly and medially. **(C)** Tension in the angled fibers of the posterior layer of the fascia is transmitted to the spinous processes in opposing directions, resisting separation of the spinous processes. **(D)** Diagrammatic representation of a lateral pull at the lateral raphe, resulting in tension between the lumbar spinous processes that oppose separation, thus providing stability to the spine. *(A–C. Adapted from Bogduck and MacIntosh,[7] pp. 166–167, 169, with permission. D. Adapted from Gracovetsky et al.,[22] p. 319, with permission.)*

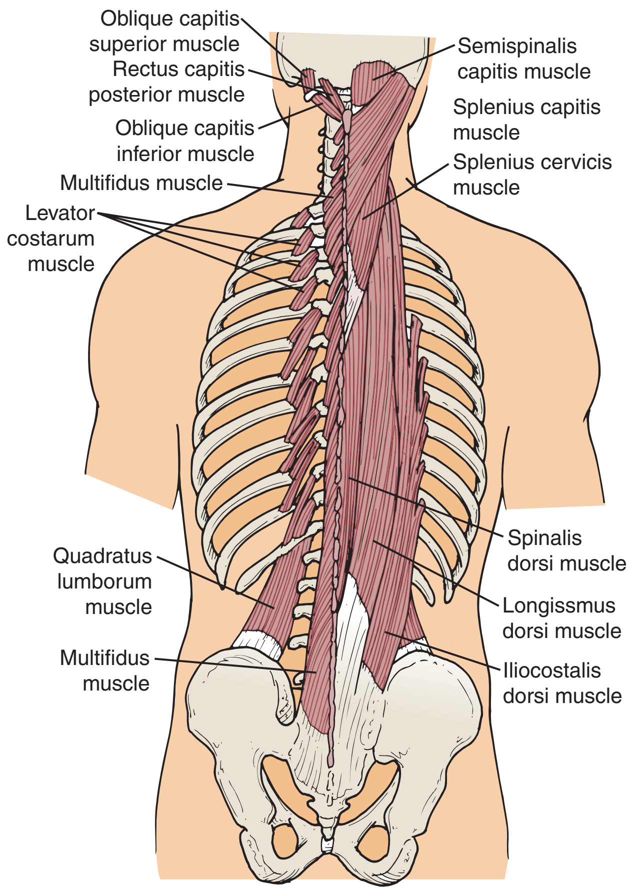

FIGURE 14.13 Muscles of the back.

multifidus, along with the erector spinae, are encased by the posterior and middle layers of the lumbodorsal fascia (see Fig. 14.11), so bulk and muscle contraction increase tension on the fascia, adding to the stabilizing function of the fascia (see below for a description of this mechanism).

In patients with low back impairment, the fibers of the multifidi quickly atrophy at the spinal segment,[28] and a moth-eaten appearance has been reported in patients undergoing surgery for lumbar disc disease.[60] Evidence supports the idea that training with specific exercises increases the function of the multifidi as well as the erector spinae in general.[15,27,29] Other deep muscles that theoretically play a role in segmental stability but to this point in time have been difficult to assess because of their depth include the intersegmental muscles (rotators and intertransversarii muscles) and deep fibers of the quadratus lumborum.

Thoracolumbar (lumbodorsal) fascia. The thoracolumbar fascia is an extensive fascial system in the back that consists of several layers.[7,8,22–24] It surrounds the erector spinae, multifidi, and quadratus lumborum, thus providing support to these muscles when they contract[23] (see Fig. 14.11). Increased bulk in these muscles increases tension in the fascia, perhaps contributing the stabilizing function of these muscles.

The aponeurosis of the latissimus dorsi and fibers from the serratus posterior inferior, internal oblique, and transverse abdominis muscles blend together at the lateral raphe of the thoracolumbar fascia, so contraction in these muscles increases tension through the angled fascia, providing stabilizing forces for the lumbar spine[23] (see Fig. 14.12). In addition, the “X” design of the latissimus dorsi and contralateral gluteus maximus has the potential to provide stability to the lumbosacral junction.

Muscle Control in the Cervical Spine

The fulcrum of the head on the spine is through the occipital/atlas joints. The center of gravity of the head is anterior to the joint axis and therefore has a flexion moment. The weight of the head is counterbalanced by the cervical extensor muscles (upper trapezius and cervical erector spinae). Tension and fatigue in these muscles, as well as in the levator scapulae (which supports the posture of the scapulae), is experienced by most people who experience postural stress to the head and neck (Fig. 14.14). The position of the mandible and the tension in the muscles of mastication are influenced by the postural relationship between the cervical spine and head.

Mandibular elevator group. The mandible is a movable structure that is maintained in its resting position with the jaw partially closed through action of the mandibular elevators (masseter, temporalis, and internal pterygoid muscles).

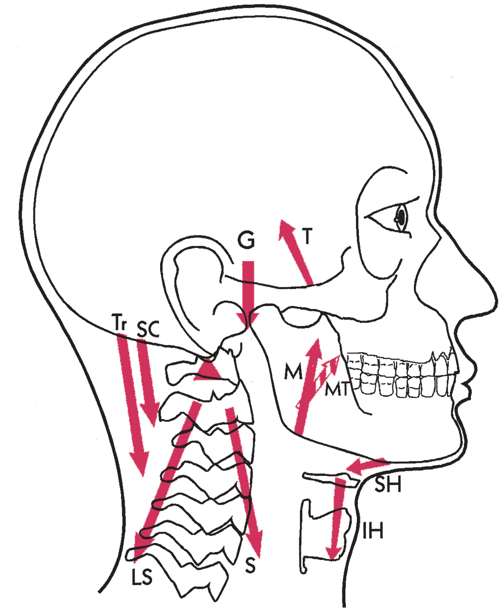

FIGURE 14.14 Head balance on the cervical spine. The posterior cervical muscles (trapezius and semispinalis capitis) counter the weight of the head. The mandibular elevating muscles (masseter, temporalis, medial pterygoid) maintain jaw elevation opposing the mandibular depression force of gravity and tension in the anterior throat muscles (suprahyoid and infrahyoid groups). The scalene and levator muscles stabilize against the posterior and anterior translatory forces on the cervical vertebrae. (Tr, trapezius; SC, semispinalis capitis; M, masseter; T, temporalis; MT, medial pterygoid; SH, suprahyoid; IH, infrahyoid; S, scalene; LS, levator scapulae; G, center of gravity; ▲, axis of motion.)

Suprahyoid and infrahyoid group. The anterior throat muscles assist with swallowing and balancing the jaw against the muscles of mastication. These muscles also function to flex the neck when rising from the supine position. With a forward head posture, they, along with the longus colli, tend to be stretched and weak so the person lifts the head with the sternocleidomastoid (SCM) muscles.

Rectus capitis anterior and lateralis, longus colli, and longus capitis (Fig. 14.15). The deep craniocervical flexor muscles have segmental attachments and provide dynamic support to the cervical spine and head.[25] The longus colli is important in the action of axial extension (retraction) and works with the SCM for cervical flexion. Without the segmental influence of the longus colli, the SCM would cause increased cervical lordosis when attempting flexion.[5]

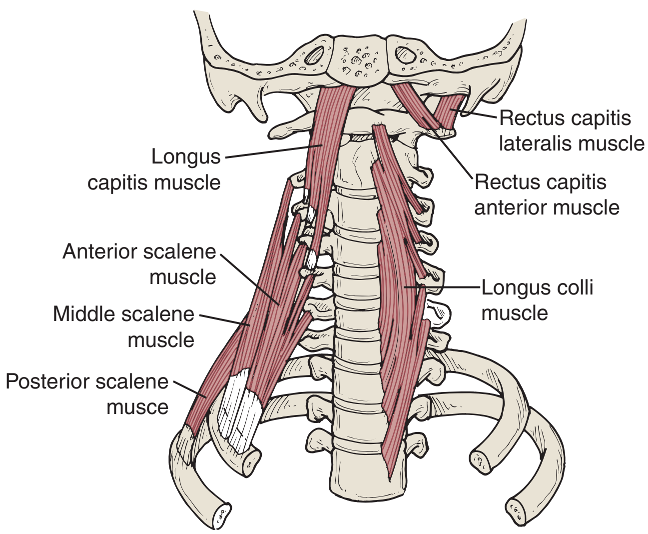

FIGURE 14.15 Deep segmental musculature in the cervical spine: rectus capitis anterior and lateralis, longus colli, longus capitis, and scalene muscles.

Multifidus. With its segmental attachments, the multifidus is thought to have a local stabilizing function in the cervical spine similar to its function in the lumbar region (see Fig. 14.13).[25]

Role of Muscle Endurance

Strength is critical for controlling large loads or responding to large and unpredictable loads (such as during heavy labor, sports, or falls), but only about 10% of maximum contraction is needed to provide stability in usual situations.[3] Slightly more might be needed in a segment damaged by disc disease or ligamentous laxity when muscles are called on to compensate for the deficit in the passive support.[3]

Greater percentages of type I fibers than type II fibers are found in all back muscles, which is reflective of their postural and stabilization functions.[53] Inactivity has been shown to change muscle fiber composition, leading to decreased muscular endurance during sustained or repetitive activities and may be one reason for decreased function in patients with low back pain.[53]

FOCUS ON EVIDENCE

In a study that looked at 17 mechanical factors and the occurrence of low back pain in 600 subjects (ages 20 through 65), poor muscular endurance in the back extensors muscles had the greatest association with low back pain.[54]

Neurological Control: Influence on Stability

The muscles of the neck and trunk are activated and controlled by the nervous system, which is influenced by peripheral and central mechanisms in response to fluctuating forces and activities. Basically, the nervous system coordinates the response of muscles to expected and unexpected forces at the right time and by the right amount by modulating stiffness and movement to match the various imposed forces.[3,16,34]

Feedforward control and spinal stability. The central nervous system activates the trunk muscles in anticipation of the load imposed by limb movement to maintain stability in the spine.[39] Research has demonstrated that there are feedforward mechanisms that activate postural responses of all trunk muscles preceding activity in muscles that move the extremities[34,37,39] and that anticipatory activation of the transversus abdominis and deep fibers of the multifidus is independent of the direction or speed of the postural disturbance.[32,33,38,50] The more superficial trunk muscles vary in response depending on the direction of arm and leg movement, reflective of their postural guy wire function, which controls displacement of the center of mass when the body changes configuration.[34,39] There are reported differences in patterns of muscle recruitment in patients with low back pain with delayed recruitment of the transversus abdominis in all movement directions and delayed recruitment of the rectus abdominis, erector spinae, and oblique abdominal muscles specific to the direction of movement compared to healthy subjects.[35]

FOCUS ON EVIDENCE

A study by Allison and associates[1] collected data from muscle activity of the TrA, internal obliques, erector spinae, and multifidus muscle groups bilaterally in seven subjects and provided evidence that challenges the concept of bilateral feed forward symmetry in the activation of the TrA, and that also contradicts previously published studies that contraction of the TrA is independent of the direction of arm movement causing trunk perturbations. The data supports the motor control strategy of feed-forward activity, but challenges the influence of support to the spine through symmetrical force generation due to the asymmetry in activation patterns dependent

on side and direction of arm movement and thus direction trunk perturbations. The authors acknowledge the value of TrA training but suggest further research is needed to provide explanation for the mechanism of its stabilizing action.

Effects of Limb Function on Spinal Stability

Without adequate stabilization of the spine, contraction of the limb-girdle musculature transmits forces proximally and causes motions of the spine that place excessive stresses on spinal structures and the supporting soft tissue.

CLINICAL TIP

- Stabilization of the pelvis and lumbar spine by the abdominal muscles against the pull of the iliopsoas muscle is necessary during active hip flexion to avoid increased lumbar lordosis and anterior shearing of the vertebrae.
- Stabilization of the ribs by the intercostal and abdominal muscles is necessary for an effective pushing force from the pectoralis major and serratus anterior muscles.
- Stabilization of the cervical spine by the longus colli muscle is necessary to prevent excessive lordosis from contraction of the upper trapezius as it functions with the shoulder girdle muscles in lifting and pulling activities.

Localized muscle fatigue. Localized fatigue in the stabilizing spinal musculature may occur with repetitive activity or heavy exertion or when the musculature is not utilized effectively due to faulty postures. There is a greater chance of injury in the supporting structures of the spine when the stabilizing muscles fatigue. Marras and Granata[47] reported significant changes in motion patterns between the spine and lower extremity joints as well as significant changes in muscle recruitment patterns with repetitive lifting during an extended period of time, resulting in increased anterior/posterior shear in the lumbar spine.

Muscle imbalances. Imbalances in the flexibility and strength of the hip, shoulder, and neck musculature cause asymmetrical forces on the spine and affect posture. Common problems are described in the section later in this chapter on "Common Faulty Postures."

Effects of Breathing on Posture and Stability

Inspiration and thoracic spine extension elevate the rib cage and assist with posture. The intercostal muscles function as postural muscles to stabilize and move the ribs. They act as a dynamic membrane between the ribs to prevent sucking in and blowing out of the soft tissue with the pressure changes during respiration.[4] The stabilizing function of the TrA also works in conjunction with the diaphragm in a feed-forward response to rapid arm motions. Contraction of the diaphragm and increased intra-abdominal pressure occur prior to rapid arm movement, irrespective of the phase of respiration or the direction of the arm motion.[34,36] The tonic activities of the TrA and diaphragm are modulated to meet respiratory demands during both inspiration and expiration and provide stability to the spine when there are repetitive limb movements.[30,31]

Effects of Intra-abdominal Pressure and the Valsalva Maneuver on Stability

During the Valsalva maneuver, contraction of the TrA, IO, and EO muscles increase intra-abdominal pressure (IAP).[11] Contraction of the TrA alone pushes the abdominal contents up against the diaphragm; therefore, to complete the enclosed chamber, the diaphragm and pelvic floor muscles contract in synchrony with the TrA.[52] There are several ideas that explain how IAP improves spinal stability. The increased pressure in the enclosed chamber may act to unload the compressive forces on the spine as well as increase the stabilizing effect by pushing out against the abdominal muscles, increasing their length-tension relationship and tension on the thoracolumbar fascia (Figs. 14.16 and 14.17).[63] It is also suggested that the IAP may act to prevent buckling of the spine and thus prevent tissue strain or failure.[10]

The Valsalva maneuver is a technique frequently used by individuals lifting heavy loads and potentially has cardiovascular risks (see Chapter 6), so it is recommended that individuals be

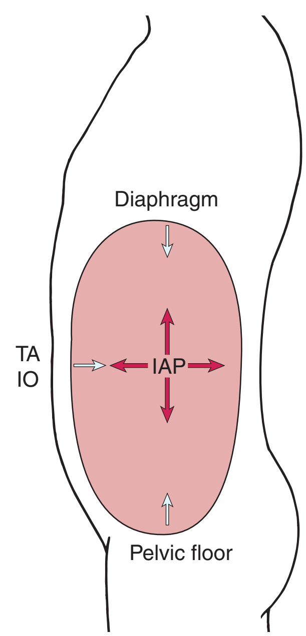

FIGURE 14.16 Coordinated contraction of the transversus abdominis, diaphragm, and pelvic floor musculature increases intra-abdominal pressure, which unloads the spine and provides stability.

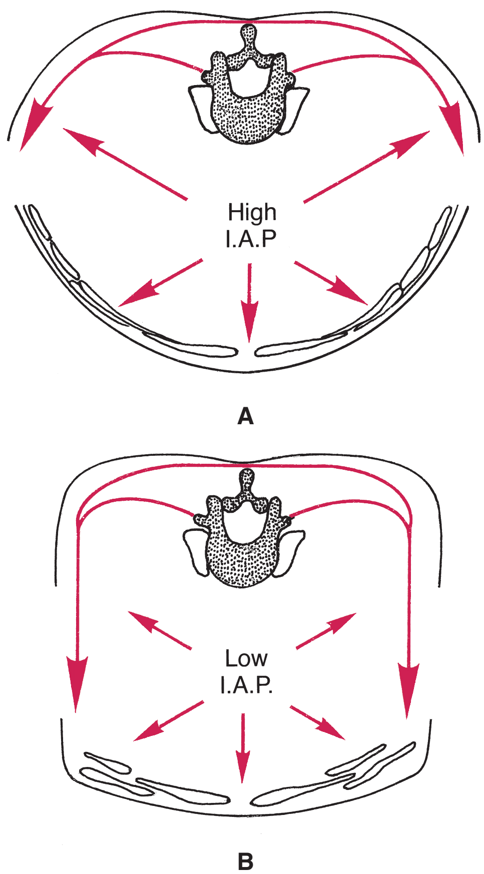

FIGURE 14.17 (A) Increased intra-abdominal pressure (IAP) pushes outward against the transversus abdominis and internal obliques, creating increased tension on the thoracolumbar fascia, resulting in improved spinal stability. **(B)** Reduced pressure decreases the stabilizing effect. *(Adapted from Gracovetsky,[24] p. 114, with permission.)*

taught to exhale while maintaining the abdominal contractions to decrease the risks. In addition, Hodges and associates[36] found that if a static expulsive effort is maintained (holding the breath while contracting the abdominal muscles), activation of the transverse abdominis is delayed. Because activation of the transversus abdominis is necessary for segmental spinal stability, expiration during exertion reinforces this stabilizing function.

Impaired Posture

In order to make sound clinical decisions when managing patients with activity or participation restrictions (functional limitations) due to spinal impairments, it is necessary to understand the underlying effects of faulty posture on flexibility, strength, and the pain experienced by the individual. Impaired posture may be the underlying cause of the patient's pain or may be the result of some traumatic or pathological event. In this section, the etiology of pain and common faulty postures are described in detail followed by guidelines for developing therapeutic exercise interventions. Impaired posture is classified in *The Guide to Physical Therapist Practice*, second edition, under "Musculoskeletal Diagnostic Classification Pattern B: Impaired Posture."[1a]

Etiology of Pain

Effect of Mechanical Stress

The ligaments, facet capsules, periosteum of the vertebrae, muscles, anterior dura mater, dural sleeves, epidural areolar adipose tissue, and walls of blood vessels are innervated and responsive to nociceptive stimuli.[14] Mechanical stress to pain-sensitive structures, such as sustained stretch to ligaments or joint capsules or compression of blood vessels, causes distention or compression of the nerve endings, which leads to the experience of pain. This type of stimulus occurs in the absence of an inflammatory reaction. It is not a pathological problem but a mechanical one because signs of acute inflammation with constant pain are not present.

Relieving the stress to the pain-sensitive structure relieves the pain stimulus, and the person no longer experiences pain. If the mechanical stresses exceed the supporting capabilities of the tissues, breakdown ensues. If it occurs without adequate healing, musculoskeletal disorders or overuse syndromes with inflammation and pain affect function without an apparent injury (see Chapter 10). Relieving the mechanical stress (i.e., correcting the posture) along with decreasing the inflammation is important.

Effect of Impaired Postural Support from Trunk Muscles

Little muscle activity is required to maintain upright posture; but with total relaxation of muscles, the spinal curves become exaggerated, and passive structural support is called on to maintain the posture. When there is continued end-range loading, strain occurs with creep and fluid redistribution in the supporting tissues, making them vulnerable to injury.[66]

Continual exaggeration of the curves leads to postural impairment and muscle strength and flexibility imbalances as well as other soft tissue restrictions or hypermobility. Muscles that are habitually kept in a stretched position tend to test weaker because of a shift in the length-tension curve; this is known as *stretch weakness*.[41] Muscles kept in a habitually shortened position tend to lose their elasticity. These muscles test strong only in the shortened position but become weak as they are lengthened.[21] This condition is known as *tight weakness*.[21]

Effect of Impaired Muscle Endurance

Endurance in muscles is necessary to maintain postural control. Sustained postures require continual, small adaptations in the stabilizing muscles to support the trunk against fluctuating forces. Large, repetitive motions also require muscles to respond so as to control the activity. In either case, as the muscles fatigue, the mechanics of performance change and

the load is shifted to the inert tissues supporting the spine at the end-ranges.[65] With poor muscular support and a sustained load on the inert supporting tissues, creep and distention occur, causing mechanical stress. In addition, injuries occur more frequently after a lot of repetitive activity or long periods of work and play when there is muscle fatigue.

Pain Syndromes Related to Impaired Posture

Postural fault. A postural fault is a posture that deviates from normal alignment but has no structural impairments.

Postural pain syndrome. Postural pain syndrome refers to the pain that results from mechanical stress when a person maintains a faulty posture for a prolonged period; the pain is usually relieved with activity. There are no impairments in functional strength or flexibility, but if the faulty posture continues, strength and flexibility imbalances eventually develop.

Postural dysfunction. Postural dysfunction differs from postural pain syndrome in that adaptive shortening of soft tissues and muscle weakness are involved. The cause may be prolonged poor postural habits, or the dysfunction may be a result of contractures and adhesions formed during the healing of tissues after trauma or surgery. Stress to the shortened structures causes pain. In addition, strength and flexibility imbalances may predispose the area to injury or overuse syndromes that a normal musculoskeletal system could sustain.

Postural habits. Good postural habits in the adult are necessary to avoid postural pain syndromes and postural dysfunction. Also, careful follow-up in terms of flexibility and posture training exercises is important after trauma or surgery to prevent impairments from contractures and adhesions. In the child, good postural habits are important to avoid abnormal stresses on growing bones and adaptive changes in muscle and soft tissue.

Common Faulty Postures: Characteristics and Impairments

The head, neck, thorax, lumbar spine, and pelvis are all interrelated; and deviations in one region affect the other areas. For clarity of presentation, the lumbopelvic and cervicothoracic regions and typical muscle length-strength impairments for each region are described separately in this section.

Pelvic and Lumbar Region

Lordotic Posture

Lordotic posture (Fig. 14.18 A) is characterized by an increase in the lumbosacral angle (the angle that the superior border of the first sacral vertebral body makes with the horizontal, which optimally is 30°), an increase in lumbar lordosis, and an increase in the anterior pelvic tilt and hip flexion. It is often

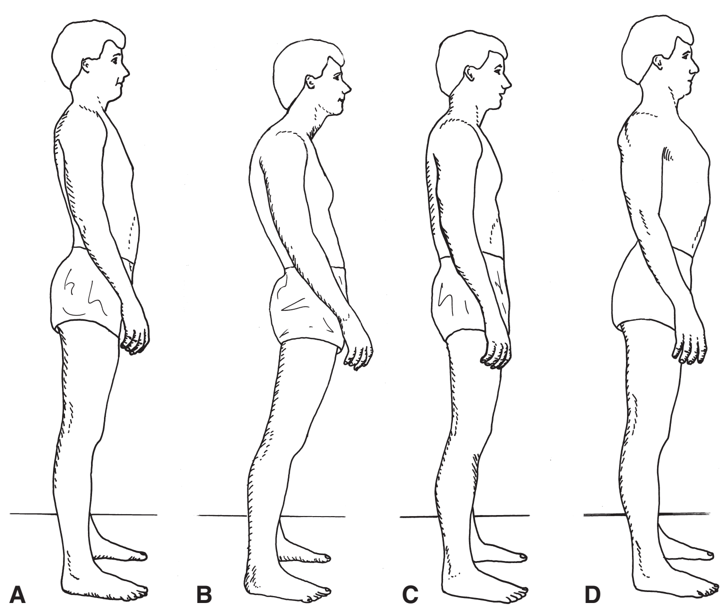

FIGURE 14.18 (A) Lordotic posture characterized by an increase in the lumbosacral angle, increased lumbar lordosis, increased anterior tilting of the pelvis, and hip flexion. **(B)** Relaxed or slouched posture characterized by excessive shifting of the pelvic segment anteriorly, resulting in hip extension, and shifting of the thoracic segment posteriorly, resulting in flexion of the thorax on the upper lumbar spine. A compensatory increased thoracic kyphosis and forward head placement are also seen. **(C)** Flat low-back posture characterized by a decreased lumbosacral angle, decreased lumbar lordosis, and posterior tilting of the pelvis. **(D)** Flat upper back and cervical spine characterized by a decrease in the thoracic curve, depressed scapulae, depressed clavicle, and an exaggeration of axial extension (flexion of the occiput on the atlas and flattening of the cervical lordosis).

seen with increased thoracic kyphosis and forward head and is called kypholordotic posture.[41]

Potential Muscle Impairments

- Mobility impairment in the hip flexor muscles (iliopsoas, tensor fasciae latae, rectus femoris) and lumbar extensor muscles (erector spinae)
- Impaired muscle performance due to stretched and weak abdominal muscles (rectus abdominis, internal and external obliques, and transversus abdominis)

Potential Sources of Symptoms

- Stress to the anterior longitudinal ligament.
- Narrowing of the posterior disc space and narrowing of the intervertebral foramen. This may compress the dura and blood vessels of the related nerve root or the nerve root itself, especially if there are degenerative changes in the vertebra or intervertebral disc.
- Approximation of the articular facets. Weight bearing through the facets may increase, which may cause synovial irritation and joint inflammation and may eventually accelerate degenerative changes if not corrected.

Common Causes

Sustained faulty posture, pregnancy, obesity, and weak abdominal muscles are common causes.

Relaxed or Slouched Posture

The relaxed or slouched posture (Fig. 14.18 B) is also called swayback.[41] The amount of pelvic tilting is variable, but usually there is a shifting of the entire pelvic segment anteriorly, resulting in hip extension, and shifting of the thoracic segment posteriorly, resulting in flexion of the thorax on the upper lumbar spine. This results in increased lordosis in the lower lumbar region, increased kyphosis in the thoracic region, and usually a forward head. The position of the mid and upper lumbar spine depends on the amount of displacement of the thorax. When standing for prolonged periods, the person usually assumes an asymmetrical stance in which most of the weight is borne on one lower extremity with pelvic drop (lateral tilt) and hip abduction on the unweighted side. This affects frontal plane symmetry.

A sitting slouched posture occurs when there is an overall kyphotic curve throughout the entire thoracic and lumbar spine.

Potential Muscle Impairments

- Mobility impairment in the upper abdominal muscles (upper segments of the rectus abdominis and obliques), internal intercostal, hip extensor, and lower lumbar extensor muscles and related fascia
- Impaired muscle performance due to stretched and weak lower abdominal muscles (lower segments of the rectus abdominis and obliques), extensor muscles of the lower thoracic region, and hip flexor muscles

Potential Sources of Symptoms

- Stress to the iliofemoral ligaments, the anterior longitudinal ligament of the lower lumbar spine, and the posterior longitudinal ligament of the upper lumbar and thoracic spine. With asymmetrical postures, there is also stress to the iliotibial band on the side of the elevated hip. Other frontal plane asymmetries may also be present and are described in the following section.
- Narrowing of the intervertebral foramen in the lower lumbar spine that may compress the blood vessels, dura, and nerve roots, especially with arthritic conditions.
- Approximation of articular facets in the lower lumbar spine.

Common Causes

As the name implies, this is a relaxed posture in which the muscles are not used to provide support. The person yields fully to the effects of gravity, and only the passive structures at the end of each joint range (e.g., ligaments, joint capsules, boney approximation) provide stability. Causes may be attitudinal (the person feels comfortable when slouching), fatigue (seen when required to stand for extended periods), or muscle weakness (the weakness may be the cause or the effect of the posture). A poorly designed exercise program—one that emphasizes thoracic flexion without balancing strength with other appropriate exercises and postural training—may perpetuate these impairments.

Flat Low-Back Posture

Flat low-back posture (Fig. 14.18 C) is characterized by a decreased lumbosacral angle, decreased lumbar lordosis, hip extension, and posterior tilting of the pelvis.

Potential Muscle Impairments

- Mobility impairment in the trunk flexor (rectus abdominis, intercostals) and hip extensor muscles
- Impaired muscle performance due to stretched and weak lumbar extensor and possibly hip flexor muscles

Potential Sources of Symptoms

- Lack of the normal physiological lumbar curve, which reduces the shock-absorbing effect of the lumbar region and predisposes the person to injury
- Stress to the posterior longitudinal ligament
- Increase of the posterior disc space, which allows the nucleus pulposus to imbibe extra fluid and, under certain circumstances, may protrude posteriorly when the person attempts extension. This increased weight bearing on the disc may lead to degenerative changes.

Common Causes

Continued slouching or flexion in sitting or standing postures; overemphasis on flexion exercises in general exercise programs

Cervical and Thoracic Region

Round Back (Increased Kyphosis) with Forward Head

The round back with forward head posture (see Fig. 14.18 B) is characterized by an increased thoracic curve, protracted scapulae (round shoulders), and forward (protracted) head.

A forward head involves increased flexion of the lower cervical and the upper thoracic regions, increased extension of the upper cervical vertebra, and extension of the occiput on C1. There also may be temporomandibular joint dysfunction with retrusion and depression of the mandible.

Potential Muscle Impairments

- Mobility impairment in the muscles of the anterior thorax (intercostal muscles), muscles of the upper extremity originating on the thorax (pectoralis major and minor, latissimus dorsi, serratus anterior), muscles of the cervical spine and head that attached to the scapula and upper thorax (levator scapulae, sternocleidomastoid, scalene, upper trapezius), and muscles of the suboccipital region (rectus capitis posterior major and minor, obliquus capitis inferior and superior)
- Impaired muscle performance due to stretched and weak lower cervical and upper thoracic erector spinae and scapular retractor muscles (rhomboids, middle trapezius), anterior throat muscles (suprahyoid and infrahyoid muscles), and capital flexors (rectus capitis anterior and lateralis, superior oblique longus colli, longus capitis)
- With temporomandibular joint symptoms, the muscles of mastication (pterygoid, masseter, temporalis muscles) may experience increased tension.

Potential Sources of Symptoms

- Stress to the anterior longitudinal ligament in the upper cervical spine and to the posterior longitudinal ligament and ligamentum flavum in the lower cervical and thoracic spine
- Fatigue of the thoracic erector spinae and scapular retractor muscles
- Irritation of facet joints in the upper cervical spine
- Narrowing of the intervertebral foramina in the upper cervical region, which may impinge on the blood vessels and nerve roots, especially if there are degenerative changes.
- Impingement on the neurovascular bundle from anterior scalene or pectoralis minor muscle tightness (see "Thoracic Outlet Syndrome" in Chapter 13)
- Strain on the neurovascular structures of the thoracic outlet from scapular protraction[40]
- Impingement of the cervical plexus from levator scapulae muscle tightness
- Impingement on the greater occipital nerves from a tight or tense upper trapezius muscle, leading to tension headaches
- Temporomandibular joint pain from joint compression due to mandibular malalignment and associated facial muscle tension
- Lower cervical disc lesions from the faulty flexed posture

Common Causes

- The effects of gravity, slouching, and poor ergonomic alignment in the work or home environment. Occupational or functional postures requiring leaning forward or tipping the head backward for extended periods; faulty sitting postures, such as working at an improperly placed computer keyboard or screen, relaxed postures, or the end result of a faulty pelvic and lumbar spine posture are common causes of forward head posture. Causes are similar to the relaxed lumbar posture or the flat low-back posture in which there is continued slouching and overemphasis on flexion exercises in general exercise programs.

Flat Upper Back and Neck Posture

The flat upper back and neck posture (Fig. 14.18 D) is characterized by a decrease in the thoracic curve, depressed scapulae, depressed clavicles, and decreased cervical lordosis with increased flexion of the occiput on atlas. It is associated with an exaggerated military posture but is not a common postural deviation. There may be temporomandibular joint dysfunction with protraction of the mandible.

Potential Muscle Impairments

- Mobility impairment in the anterior neck muscles, thoracic erector spinae, and scapular retractors, and potentially restricted scapular movement, which decreases the freedom of shoulder elevation
- Impaired muscle performance in the scapular protractor and intercostal muscles of the anterior thorax

Potential Sources of Symptoms

- Fatigue of muscles required to maintain the posture
- Compression of the neurovascular bundle in the thoracic outlet between the clavicle and ribs
- Temporomandibular joint pain and occlusive changes
- Decrease in the shock-absorbing function of the kypholordotic curvature, which may predispose the neck to injury

Common Cause

As noted, this is not a common postural deviation and occurs primarily with exaggeration of the military posture.

Frontal Plane Deviations: Scoliosis and Lower Extremity Asymmetries

Scoliosis

Scoliosis is defined as a lateral curvature in the spine. It usually involves the thoracic and lumbar regions. Typically, in right-handed individuals, there is a mild right thoracic, left lumbar S-curve, or a mild left thoracolumbar C-curve. There may be asymmetry in the hips, pelvis, and lower extremities.

Structural scoliosis. *Structural scoliosis* involves an irreversible lateral curvature with fixed rotation of the vertebrae (Fig. 14.19 A). Rotation of the vertebral bodies is toward the convexity of the curve. In the thoracic spine, the ribs rotate with the vertebrae, so there is prominence of the ribs posteriorly on the side of the spinal convexity and prominence anteriorly on the side of the concavity. A posterior rib hump is detected on forward bending in structural scoliosis (Fig. 14.19 B).[44]

Nonstructural scoliosis. *Nonstructural scoliosis* is reversible and can be changed with forward or side bending and with positional changes, such as lying supine, realignment of the pelvis by correction of a leg-length discrepancy, or with muscle contractions. It is also called *functional* or *postural scoliosis.*

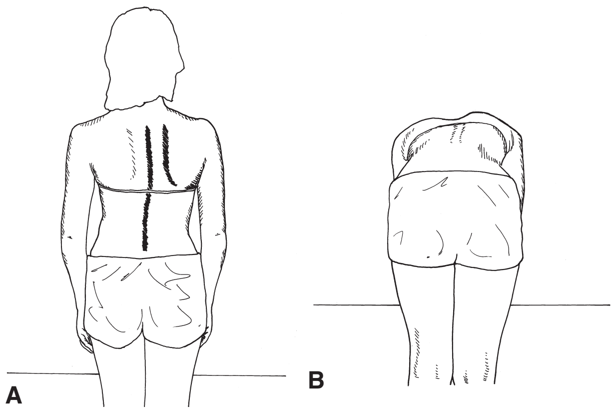

FIGURE 14.19 (A) Mild right thoracic left lumbar structural scoliosis with prominence of the right scapula. **(B)** Forward bending produces a slight posterior rib hump, indicating fixed rotation of the vertebrae and rib cage.

Potential Impairments

- Mobility impairment in joints, muscles, and fascia on the concave side of the curves
- Impaired muscle performance due to stretch and weakness in the musculature on the convex side of the curves
- If one hip is adducted, the adductor muscles on that side have decreased flexibility, and the abductor muscles are stretched and weak. The opposite occurs on the contralateral extremity.[41]
- With advanced structural scoliosis, there is decreased rib expansion; cardiopulmonary impairments may result in difficulty breathing.

Potential Sources of Symptoms

- Muscle fatigue and ligamentous strain on the side of the convexity
- Nerve root irritation on the side on the concavity
- Joint irritation from approximation of the facets on the side of the concavity

Common Causes: Structural Scoliosis

Neuromuscular diseases or disorders (e.g., cerebral palsy, spinal cord injury, progressive neurological or muscular diseases), osteopathic disorders (e.g., hemivertebra, osteomalacia, rickets, fracture), and idiopathic disorders in which the cause is unknown are common causes of structural scoliosis.

Common Causes: Nonstructural Scoliosis

Leg-length discrepancy (structural or functional), muscle guarding or spasm from a painful stimuli in the back or neck, and habitual or asymmetrical postures are common causes of nonstructural scoliosis.

Frontal Plane Deviations from Lower Extremity Asymmetries

Any lower extremity inequality has an effect on the pelvis that, in turn, affects the spinal column and structures supporting it.[18] When dealing with spinal posture, it is imperative to assess lower extremity alignment, symmetry, foot posture, ROM, muscle flexibility, and strength. See Chapters 20 through 22 for principles, procedures, and techniques for treating the hip, knee, ankle, and foot. Frontal plane deviations may also be seen with faulty postural habits such as perpetually standing with a pelvic drop on one side as frequently seen with relaxed postures. This may result in muscle imbalances in the hip and spine and an apparent leg-length discrepancy.

Characteristic Deviations (Fig. 14.20)

When standing with weight equally distributed to both lower extremities, an elevated ilium on the long leg (LL) side and lowered on the short leg (SL) side is the characteristic deviation.

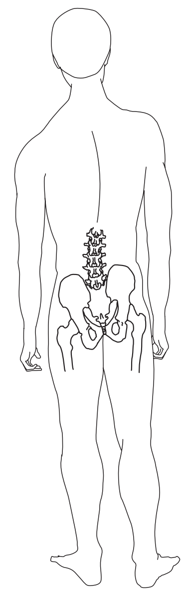

FIGURE 14.20 Frontal plane asymmetries. Pictured is an individual with a long leg and elevated ilium on the right side. Typically, hip adduction, vertical sacroiliac (SI) joint, side bending toward and rotation opposite that of the lumbar spine, and compensations in thoracic and cervical spine are seen on the long-leg side.

- This puts the LL side in hip adduction with greater shear stress and the SL side in hip abduction with greater compression stress.
- The sacroiliac (SI) joint on the LL side is more vertical with greater shear stress; on the SL side, it is more horizontal with greater compression stress.
- Side bending of the lumbar spine toward the LL side coupled with rotation in the opposite direction
- This compresses the intervertebral disc on the LL side and distracts the disc on the SL side; it also causes torsional stress.
- There is extension and compression of the lumbar facets on the LL side (concave portion of the curve) and flexion and distraction of the lumbar facets on the SL side (convex portion of the curve).
- There is narrowing of the intervertebral foramina on the LL side.
- The thoracic and cervical spine has compensatory scoliosis in the opposite direction.

Potential Muscle Impairments

- Mobility impairment from decreased flexibility in the hip adductors on the LL side and abductors on the SL side. There may also be asymmetrical differences in the iliopsoas, quadratus lumborum, piriformis, erector spinae, and multifidus muscles, with those on the concave side of the curve or the LL side having decreased flexibility.
- Impaired muscle performance from stretched and weakened muscles that typically includes hip adductors on the SL side, abductors on the LL side, and in general muscles on the convex side of the curve.

Potential Sources of Symptoms

- Greater shear forces occur in the hip and SI joints on the LL side, which increases stress in the supporting ligaments and decreases the load-bearing surface in the joint. Degenerative changes occur more frequently in hips on the LL side.[17]
- Stenosis in the lumbar intervertebral foramina on the LL side may cause vascular congestion or nerve root irritation.
- Lumbar facet compression and irritation on the LL side leading to early degenerative changes.
- Intervertebral disc breakdown from torsional and asymmetrical forces.
- Muscle tension, fatigue, or spasm in response to asymmetrical loading and response.
- Lower extremity overuse syndromes.

Common Causes

Asymmetry in the lower extremities may result from structural or functional deviations at the hip, knee, ankle, or foot. Common functional problems include unilateral flat foot and imbalances in the flexibility of muscles. The resulting asymmetrical ground reaction forces transmitted to the pelvis and back may lead to tissue breakdown and overuse, particularly as a person ages, becomes overweight, or is generally deconditioned from inactivity.

Management of Impaired Posture

Faulty posture underlies many spinal and extremity disorders and functional restrictions. Often by simply correcting the underlying postural stresses, the primary symptoms can be minimized or even alleviated. Because of this the following guidelines may become part of most rehabilitation programs. Exercises for use with postural impairments are identified in this section and are described in detail in the respective chapters that follow.

General Management Guidelines

Before developing a plan of care and selecting interventions for management, evaluate the findings from the examination of the patient, including the history, review of systems, and specific tests and measures, and document the findings.

- Postural alignment (sitting and standing), balance, and gait
- ROM, joint mobility, and flexibility
- Muscular strength and endurance for repetitions and holding
- Ergonomic assessment if indicated
- Body mechanics
- Cardiopulmonary endurance/aerobic capacity, breathing pattern

Common impairments and a summary of the information that follows on management of patients with impaired posture are summarized in Box 14.1.

Awareness and Control of Spinal Posture

Initially, good spinal posture may be prevented because of restricted mobility of muscle, connective tissue, or vertebral segment, but developing patient awareness of balanced posture and its effects should begin as soon as possible in the treatment program in conjunction with stretching and muscle-training maneuvers.

Posture Training Techniques

Isolate each body segment and train the patient to properly move that segment. If one region is out of alignment, it is likely that there are compensatory deviations in the alignment throughout the spine. Therefore, total posture correction, including upper and lower extremity alignment, should be emphasized. Direct the patient's attention to the feel of proper movement and muscle contraction and relaxation. Another technique is to have the patient assume an extreme corrected posture, then ease away from the extreme toward midposition, and finally hold the corrected posture. Use verbal, tactile, and visual reinforcement cues such as:

- ***Verbal reinforcement.*** As you interact with the patient, frequently interpret the sensations of muscle contraction and spinal positions that he or she should be feeling.
- ***Tactile reinforcement.*** Help the patient position the head and trunk in correct alignment and touch the muscles that need to contract to move and hold the parts in place.
- ***Visual reinforcement.*** Use mirrors so the patient can see how he or she looks, what it takes to assume correct alignment, and then how it feels when properly aligned.

Axial Extension (Cervical Retraction) to Decrease a Forward Head Posture

Patient position and procedure: Sitting or standing, with arms relaxed at the side. Lightly touch above the lip under the nose and ask the patient to lift the head up and away as if a string was pulling their head upward (Fig. 14.21 A). Verbally reinforce the correct posture, and draw attention to the way it feels. Have the patient move to the extreme of the correct posture and then return to midline.

BOX 14.1 MANAGEMENT GUIDELINES—
Impaired Posture

Structural and Functional Impairments

- Pain from mechanical stress to sensitive structures and from muscle tension
- Impaired mobility from muscle, joint, or fascial restrictions
- Impaired muscle performance associated with an imbalance in muscle length and strength between antagonistic muscle groups
- Impaired muscle performance associated with poor muscular endurance
- Insufficient postural control of scapular and trunk stabilizing muscles
- Decreased cardiopulmonary endurance
- Altered kinesthetic sense of posture associated with poor neuromuscular control and prolonged faulty postural habits
- Lack of knowledge of healthy spinal control and mechanics

Plan of Care	Intervention
1. Develop awareness and control of spinal posture	1. Kinesthetic training; cervical and scapular motions, pelvic tilts, control of neutral spine. Utilize procedures to develop and reinforce control of posture when sitting, standing, walking, and performing targeted functional activities
2. Educate the patient about the relationship between faulty posture and symptoms	2. Practice positions and movements to experience control of symptoms with various postures
3. Increase mobility in restricting muscles, joints, fascia	3. Manual stretching and joint mobilization/manipulation; teach self-stretching
4. Develop neuromuscular control, strength, and endurance in postural and extremity muscles	4. Stabilization exercises; progress repetitions and challenge with extremity motions; progress to dynamic trunk strengthening exercises
5. Teach safe body mechanics	5. Functional exercises to prepare for safe mechanics (squatting, lunges, reaching, pushing/pulling, lifting and turning loads with stable spine)
6. Ergonomic assessment of home, work, recreational environments	6. Adapt work, home, recreational environment
7. Stress management/relaxation	7. Relaxation exercises and postural stress relief
8. Identify safe aerobic activities	8. Implement and progress an aerobic exercise program
9. Promote healthy exercise habits for self-maintenance	9. Integration of a fitness program, regular exercise, and safe body mechanics into daily life

Scapular Retraction

Patient position and procedure: Sitting or standing. For tactile and proprioceptive cues, gently resist movement of the inferior angle of the scapulae and ask the patient to pinch them together (retraction). Suggest that the patient imagine "holding a quarter between the shoulder blades." The patient should not extend the shoulders or elevate the scapulae (Fig. 14.21 B).

Pelvic Tilt and Neutral Spine

Patient position and procedure: Sitting, then standing with the back against a wall. Teach the patient to roll the pelvis forward and backward to isolate an anterior and posterior pelvic tilt. After the patient has learned to isolate the movement, instruct him or her to practice control of the pelvis and lumbar spine by moving from extreme lordosis to extreme flat back and then assume mild lordosis. Identify the mid position as the "neutral spine," so the patient becomes familiar with the term. Show that the hand should be able to easily slip between the back and the wall and that he or she can then feel the back with one side of the hand and the wall with the other side. If the patient has difficulty tilting the pelvis, suggest that he or she imagine that the pelvis is a bushel basket with a rounded bottom and the waist is the rim of the basket. Have the patient then imagine and practice tipping the "basket" forward and backward and then finding the neutral spine position.

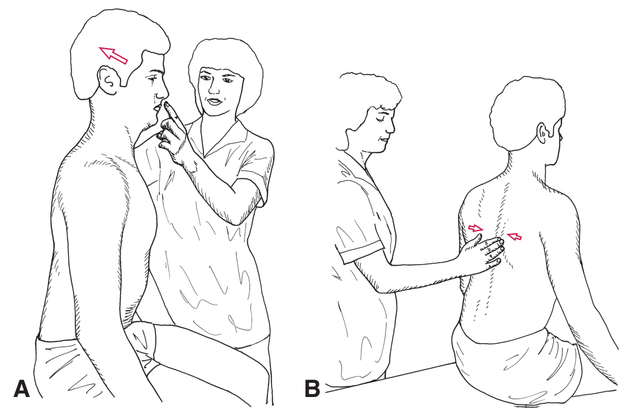

FIGURE 14.21 Training the patient to correct **(A)** forward-head posture and **(B)** protracted scapulae.

Thoracic Spine

Patient position and procedure: Standing. The position of the thorax affects the posture of the lumbar spine and pelvis; consequently, the feel of thoracic movement is incorporated in posture training for the lumbar spine. As the patient assumes a mildly lordotic posture, have him or her breathe in and lift the rib cage (extension). Guide him or her to a balanced posture, not an extremely extended posture. Standing with the back against a wall (as in the pelvic tilt training above) encourages thoracic extension.

Total Spinal Movement and Control

Patient position and procedure: Sitting or standing. Instruct the patient to curl the entire spine by first flexing the neck, then the thorax, and then the lumbar spine. Give cues for unrolling by first touching the lumbar spine as the patient extends it, then the thoracic spine as he or she extends it and takes in a breath to elevate the rib cage. Then direct attention to adducting the scapulae while you gently resist the motion and then lifting the head in axial extension while you give slight pressure against the upper lip (see Fig. 14.21). Verbally and visually reinforce the correct posture when it is obtained.

Reinforcement. It is not possible for a person always to maintain good posture. Therefore, to reinforce proper performance, teach the patient to use cues throughout the day to check posture. For example, instruct the patient to check the posture every time he or she walks past a mirror, waits at a red traffic light while driving a car, sits down for a meal, enters a room, or begins talking with someone. Find out what daily routines the patient has that could be used for reinforcement or reminders; instruct the patient to practice and report the results. Provide positive feedback as the patient becomes actively involved in the relearning process.

Postural support. If necessary, provide external support with a postural splint or tape to prevent the extreme posture of round shoulders and protracted scapulae. These supports help train correct muscle functioning by acting as a reminder for the patient to assume correct posture when he or she slouches. Also, by preventing the position of stretch from occurring, stretch weakness can be corrected. These devices should be used only on a temporary basis for training so the patient does not become dependent on them.

Posture, Movement, and Functional Relationships

Once the patient has learned how to assume correct postures, it is important to have him or her experience the effect sustained or repetitive faulty postures have on pain and function, followed by their ability to alter these affects by correcting their posture.

Relationship of impaired posture and pain. Have the patient assume the faulty posture and wait. When he or she begins to feel discomfort, point out the posture and then instruct how to correct it and notice the feeling of relief. Many patients do not accept such a simple relationship between stress and pain, so draw their attention to noticing what posture they are in (including when at work, home, driving/riding in a car, or in bed) when their symptoms develop and how they can control the discomfort with the following techniques.

Relationship of impaired posture and extremity function. Have the patient assume their faulty posture and attempt a functional activity such as reaching upward with their upper extremity, moving their lower extremity, or opening and closing their jaw. They then assume a corrected posture, repeat the same activity, and note the difference. Once the improved range and quality of movement are experienced, reinforce them, so the patient can understand the value of developing and maintaining good alignment when performing functional activities.

Joint, Muscle, and Connective Tissue Mobility Impairments

Common muscle imbalances in length and strength were described in the previous section on impaired postures. It is critical that specific mobility restrictions are identified so that stretching techniques can be selective. For example, the transition areas between the cervicothoracic, thoracolumbar, and lumbosacral regions typically have greater mobility. When faulty postural habits dominate, the segmental mobility in these areas tends to become exaggerated in the direction of the faulty posture. Stretching should proceed cautiously so as not to accentuate the problem while attempting to correct the tissues with decreased mobility. Stretching techniques for the cervical, thoracic, and lumbar regions are described in Chapter 16. Specific spinal mobilization/manipulation techniques directed at specific hypomobile segments are described in Chapters 15 and 16. Although any structure could be involved, particularly following an injury or pathological condition, the muscle flexibility impairments most typically seen are identified in Box 14.2. Included are references for self-stretching/flexibility exercises for each muscle group. Specific instructions and precautions are described in the text accompanying the pictures in the respective chapters.

BOX 14.2 Stretching Techniques for Common Mobility Impairments

- *Suboccipital region*: self-stretch with capital nodding; patient apply a gentle stretch against the occiput with the lateral border of the hand
- *Levator scapulae*: self-stretch with scapular depression and cervical flexion and rotation to the opposite side (see Fig. 17.35 in Chapter 17)
- *Scalenes*: self-stretch with axial extension, side bend neck opposite and then rotate neck toward side of restriction (see position Fig. 16.3 in Chapter 16).
- *Pectoralis major and anterior thorax*: self-stretch with corner stretches (see Fig. 17.31 in Chapter 17) or while lying supine on a foam roll placed longitudinally under the spine (see Fig. 16.1 B in Chapter 16)
- *Latissimus dorsi*: self-stretch lying supine on a foam roll, reach arms overhead (see Fig. 16.1 A in Chapter 16)
- *Lumbar and hip extensors*: self-stretch lying supine, bring knees to chest; or quadruped position, move buttocks back over the feet (see Figs. 16.13 and 16.14 in Chapter 16)
- *Lumbar flexors*: self-stretch with prone press-ups or standing back bends (see Fig. 16.15 in Chapter 16).
- *Hip Flexors*: self-stretch lying supine in Thomas position or standing in modified fencer's squat (see Figs. 20.10 and 20.11 in Chapter 20).
- *Tensor fascia lata*: self-stretch either supine, side-lying, or standing; extend, laterally rotate, then adduct the hip (see Figs. 20.19, 20.20, and 20.21 in Chapter 20).
- *Iliotibial band foam roll stretch*: side-lie on a foam roll placed perpendicular to the thigh, gently roll the thigh back and forth with body weight applying the stretch force (see Fig. 21.22 in Chapter 21).
- *Pyriformis:* self-stretch lying supine or sitting and bringing the flexed knee toward the opposite shoulder. Flex, adduct, and internally rotate the hip (see Fig. 20.15 in Chapter 20).
- *Hamstrings*: self-stretch with a straight-leg maneuver either lying supine or long-sitting (see Figs. 20.17 and 20.18 in Chapter 20).
- *Gastrocsoleus (heel cords)*: self-stretch in a forward stride position with the heel of the back leg maintained on the floor, or stand on an incline board or edge of a step (see Fig. 22.8 in Chapter 22).

Impaired Muscle Performance

Typically impaired postural muscles that support the body in sustained postures succumb to the effects of gravity, become less active,[56] and develop stretch weakness.[41] Strengthening alone does not correct this problem, so any exercises must be done in conjunction with posture training for control, as described earlier in this section. In addition, exercises for muscular endurance are necessary to prepare the muscles to function over an extended period of time. Finally, environmental adaptations must be made to minimize the stresses of sustained and repetitive postures. Muscles that typically demonstrate stretch weakness or poor postural endurance are identified in Box 14.3. In-depth descriptions of the exercises are in the chapters identified.

BOX 14.3 Training and Strengthening Techniques for Common Muscle Impairments

- Activate and learn control of the longus colli and deep capital flexors (see Figs. 16.39 B and 16.59 in Chapter 16)
- Lower cervical extension (see Fig. 16.40 in Chapter 16)
- Scapular retraction and shoulder lateral rotation (see Fig. 16.45 in Chapter 16 and Figs. 17.46 and 17.47 in Chapter 17)
- Lumbar spinal stabilization (see Figs. 16.47 through 16.56 plus accompanying text in Chapter 16)
- Hip abduction; posterior gluteus medius; begin side-lying, progress to standing. Place emphasis on maintaining the hip in extension with slight lateral rotation while abducting (see Fig. 20.26 B in Chapter 20).

Body Mechanics

Muscle strengthening for safe body mechanics includes not only strengthening specific muscles but also functional activities that prepare the body for specific stresses that it is required to do for a particular function, as identified in Box 14.4. Instruction in body mechanics is described in detail in Chapter 16 in the section "Functional Training."

Ergonomics: Relief and Prevention

It is critical to help the patient adapt postures and activities that are performed on a sustained or repetitive basis at work, at home, recreationally, or socially if they are contributing to the postural stresses and musculoskeletal disorders.[55] It may be necessary to use a lumbar pillow for support or to modify the work environment (workstation) to relieve sustained stressful postures. There are many resources, such as the Occupational Safety and Health Administration (OSHA) web site (http://www.osha.gov/SLTC/ergonomics/) and others (http://ergo.human.cornell.edu/) that provide information on ergonomic assessment and adaptation to work environments to relieve postural stress and musculoskeletal disorders.

BOX 14.4 Functional Exercises in Preparation for Safe Body Mechanics

- Upper extremity pulling and pushing (see Fig. 17.58 in Chapter 17)
- Wall slides—progress to squatting and squatting with lifting (see Fig. 20.29 in Chapter 20)
- Lunges—progress to lunges with lifting and with pushing and pulling (see Fig. 20.32 in Chapter 20 and Figs. 23.31 and 23.62 in Chapter 23).

FOCUS ON EVIDENCE

There is strong evidence, documented in a 3-year prospective study of 632 newly hired computer users, that a computer workstation may be the source of symptoms if the chair, desk, keyboard, mouse, and monitor are improperly positioned for the individual.[20,46] There is also mixed evidence, summarized in a systematic study of the literature on the relationship of posture and repetitive stresses in the work environment, regarding the development of low back pain.[69]

Stress Management/Relaxation

A component of the educational process is to teach the individual how to relax tense muscles and relieve postural stress. Muscle relaxation techniques can be incorporated throughout the day to relieve postural stress, and conscious relaxation training increases patient awareness and control over tension in the muscles.

PRECAUTION: These techniques are not appropriate for managing acute pain due to inflammation, joint swelling, or disc derangements. If the patient is recovering from a pathologic condition in the spine, caution him or her that these techniques should not increase symptoms (other than a stretching sensation in chronic conditions), especially radicular symptoms. Caution should also be used with flexion in patients with a medical diagnosis of herniated disc so that symptoms should not peripheralize.

Muscle Relaxation Techniques

Whenever discomfort develops from maintaining a constant posture or from sustaining muscle contractions for a period of time, active ROM in the opposite direction aids in taking stress off supporting structures, promoting circulation, and maintaining flexibility. All motions are performed slowly, through the full range, with the patient paying particular attention to the feel of the muscles. Repeat each motion several times. Suggest to the patient that these are mini-rest breaks or micro breaks to be done at work, home, or whenever tension, stress, or postural pain is experienced.

Cervical and Upper Thoracic Region

Patient position and procedure: Sitting with the arms resting comfortably on the lap, or standing. Instruct the patient to:

- Bend the neck forward and backward. (Backward bending is contraindicated with symptoms of nerve root compression.)
- Side bend the head in each direction; then rotate the head in each direction.
- Roll the shoulders; protract, elevate, retract, and then relax the scapulae (in a position of good posture).
- Circle the arms (shoulder circumduction). This is accomplished with the elbows flexed or extended, using either small or large circular motions with the arms pointing either forward or out to the side. Both clockwise and counterclockwise motions should be performed, but conclude the circumduction by going forward, up, around, and then back, so the scapulae end up in a retracted position. This has the benefit of helping retrain proper posture.

Lower Thoracic and Lumbar Region

Patient position and procedure: Sitting or standing. If standing, the feet should be shoulder-width apart with the knees slightly bent. Have the patient place the hands at the waist with the fingers pointing backward. Instruct the patient to:

- Extend the lumbar spine by leaning the trunk backward (see Fig. 16.9 B). This is particularly beneficial when the person must sit or stand in a forward-bent position for prolonged periods.
- Flex the lumbar spine by contracting the abdominal muscles, causing a posterior pelvic tilt; or bend the trunk forward while sitting, dangling the arms toward the floor. This motion is beneficial when the person stands in a lordotic or swayback posture for prolonged periods.
- Side bend in each direction.
- Rotate the trunk by turning in each direction while keeping the pelvis facing forward.
- Stand up and walk around at frequent intervals when sitting for extended periods.

Conscious Relaxation Training for the Cervical Region

Specific techniques in guided imagery for the cervical region develop the patient's kinesthetic awareness of a tensed or relaxed muscle and how consciously to reduce tension in the muscle. In addition, if done with posture training techniques in mind, as described earlier in the chapter, the patient can be helped to recognize decreased muscular tension when the head is properly balanced and the cervical spine is aligned in midposition.

Patient position and procedure: Sitting comfortably with arms relaxed, such as resting on a pillow placed on the lap; the eyes are closed. Position yourself next to the patient to use tactile cues on the muscles and help position the head as necessary. Have the patient perform the following activities in sequence.

- Use diaphragmatic breathing and breathe in slowly and deeply through the nose, allowing the abdomen to relax and expand; then relax and allow the air to be expired through the relaxed open mouth. This breathing is reinforced after each of the following activities.
- Next, relax the jaw. The tongue rests gently on the hard palate behind the front teeth with the jaw slightly open. If the patient has trouble relaxing the jaw, have him or her click the tongue and allow the jaw to drop. Practice until the patient feels the jaw relax and the tongue rests behind the front teeth. Follow with relaxed breathing.
- Slowly flex the neck. As the patient does so, direct the attention to the posterior cervical muscles and the sensation of how the muscles feel. Use verbal cues such as, "Notice the feeling of increased tension in your muscles as your head drops forward."

- Then slowly raise the head to neutral, inhale slowly, and relax. Help the patient position the head properly and suggest that he or she note how the muscles contract to lift the head, then relax once the head is balanced.
- Repeat the motion; again, direct the patient's attention to the feeling of contraction and relaxation in the muscles as he or she moves. Imagery can be used with the breathing such as "fill your head with air and feel it lift off your shoulders as you breathe in and relax."
- Then go through only part of the range, noting how the muscles feel.
- Next, just think of letting the head drop forward and then tightening the muscles (setting); then think of bringing the head back and relaxing. Reinforce to the patient the ability to influence the feeling of contraction and relaxation in the muscles.
- Finally, just think of tensing the muscles and relaxing, letting the tension go out of the muscles even more. Point out that he or she feels even greater relaxation. Once the patient learns to perceive tension in muscles, he or she can then consciously think of relaxing the muscles. Emphasize the fact that the position of the head also influences muscle tension. Have the patient assume various head postures and then correct them until the feeling is reinforced.

Modalities and Massage

Once acute symptoms are under control, the use of modalities and massage are minimized or decreased so the patient learns self-management through exercises, relaxation, and posture retraining and does not become dependent on external applications of interventions for comfort.

Healthy Exercise Habits

It is important to integrate a progression of postural control into all stabilization exercises, aerobic conditioning, and functional activities (see Chapter 16). The patient is carefully observed as greater challenges to activities are performed; and if necessary, reminders are provided to find the neutral spinal position and to initiate contraction of the stabilizing muscles prior to the activity. For example, when reaching overhead, the patient learns to contract the abdominal muscles to maintain a neutral spine position and not allow the spine to extend into a painful or unstable range. This is incorporated into body mechanics, such as when going from picking up and lifting to placing an object on a high shelf, or into sport activities when reaching up to block or throw a ball. Once developed under your guidance, encourage the patient to continue with a healthy lifestyle, fitness level, and body mechanics.

Independent Learning Activities

Critical Thinking and Discussion

1. What are the functional differences between the way the cervical spine and lumbar spine are used in daily activities?
2. Explain how faulty posture can cause painful symptoms.
3. Explain why a "one-size-fits-all" exercise program for posture correction cannot benefit everyone, or how it may be detrimental to some individuals. Discuss this in relation to each of the faulty postures described in this chapter.

Laboratory Practice

1. Practice identifying the effects various postures have on the various regions of the spine—that is, what happens to the cervical and lumbar spine when in supine, prone, side-lying, sitting, and standing postures; does the spine tend to move into flexion or extension? Determine what is needed to change the position; that is, if flexion is emphasized in a particular posture, what is needed to move the spine into a more neutral (mid-range) position?
2. Identify and feel what happens to the various portions of the spine when moving from one position to another (i.e., rolling supine to prone and return, moving from supine to sit, sit to stand and reverse). What happens to the lumbar spine and pelvis when walking; how is this affected if the person has a hip flexion contracture, or a contracture in the external rotators of the hip?
3. Examine the standing posture of a classmate; then examine the joint ROM, muscle flexibility, and muscle strength. Identify any muscle imbalances in length and strength; then design an intervention program to influence change in the impairments. Use the guidelines presented in this chapter and summarized in Box 14.1 as well as Chapters 16 through 22 for suggested exercises and their safe application.
4. Identify and compare the similarities and differences in flexibility and muscle weakness between a person with excessive lumbar lordosis and an anterior pelvic tilt and a person with a slouched posture who stands with the pelvis shifted forward and the thorax flexed. What effect does each pelvic posture have on the hip position, and what muscles would develop restricted mobility? Usually in the slouched posture the thorax and upper lumbar spine are flexed; would the curl-up exercise be beneficial, or would it contribute to this problem? Develop an exercise program that addresses the common flexibility and strength impairments without reinforcing the faulty posture.

Case Studies

Case 1

Your patient is a 35-year-old computer programmer who is referred to you because of pain symptoms in the right cervical, posterior shoulder, and arm regions. The symptoms get

progressively worse when at work; usually the pain begins within 1 hour, and it is 6/10 by lunchtime. The same cycle occurs in the afternoon. There is occasional "tingling" in the thumb and index finger. The symptoms have progressively worsened over the last 3 months, ever since being placed in a priority job. Recreational activities include tennis and reading; the tennis does not cause symptoms, but reading makes the neck pain worse.

Examination reveals forward head and round shoulder posture. Capital flexion 50% range, cervical rotation and side bending are each 80% range, shoulder external rotation is 75°. There is restricted flexibility in the pectoralis major, pectoralis minor, levator scapulae, and scalene muscles. Cervical quadrant test reproduces the tingling in the right hand; all other neurological tests are negative. Strength of the suprahyoid and infrahyoid muscles, scapular retractors, and shoulder lateral rotators is 4/5.

- What is provoking the patient's symptoms and signs? What are the functional limitations? What is the prognosis?
- Identify impairment and functional outcome goals.
- Establish a program of intervention. How can you progress this person to functional independence?

Case 2

A 51-year-old auto mechanic is referred to physical therapy because of pain symptoms in the left buttock and posterior thigh. The symptoms are worse when standing and reaching overhead for more than 15 minutes, which is what he does when working on a car that is up on the racks. Carrying heavy objects (> 50 lb), standing, and walking for more than a half-hour increase the symptoms. There is no precipitating incident, but the symptoms have been recurrent over the past year. Symptoms also increase with the recreational activity of backpacking. Symptoms ease when in the rocker recliner, lying on a couch with knees bent, or when hugging knees to chest.

Examination reveals swayback posture when standing; decreased flexibility in the low back, gluteus maximus, hamstrings (straight leg raising to 60°), and upper abdominals; and increased pain with backward bending. Strength of the lower abdominals is 3/5. He is able to do repetitive lunges and partial squats for a maximum of 20 seconds.

- What is provoking the patient's symptoms and signs? What are the functional limitations? What is the prognosis?
- Identify impairment and functional outcome goals.
- Establish a program of intervention. Use the taxonomy of motor tasks discussed in Chapter 1 (see Figs. 1.6 and 1.7 and accompanying text) to develop a progression of exercises and tasks to progress this person to functional independence.

CHAPTER

15

The Spine: Management Guidelines

CAROLYN KISNER, PT, MS ■ JACOB N. THORP, PT, DHS, MTC

In theory, treating impairments and activity limitations (functional limitations) related to the tissues of the spinal column and trunk is the same as treating tissue injuries of the extremities. The major complicating factor in the spine is the close proximity of key structures to the spinal cord and nerve roots. The challenge for the therapist is to recognize the complex functional relationships of the facet joints, the intervertebral joints, the muscles, the fascia, and the nervous system and know how to examine and evaluate the individual who presents with pain and functional limitations. Activity, rather than prolonged bed rest, is accepted as important in the management of patients with spinal and postural pain[2,111,161] but defining what are beneficial and safe activities during the process of healing and rehabilitation is the task of the therapist.

The medical model of diagnosis does not lend itself to direct therapeutic exercise intervention strategies, particularly because patients' complaints of back or neck pain often do not relate to specific pathologies. Efforts are being made to determine the most effective way to categorize patients with symptoms affecting spine and trunk function in order to be more accurate with outcome research.[23,33,48,101,102,138,145] In addition, results from research studies have begun to provide the criteria for predicting outcomes in subgroups of patients with back and neck pain, so therapists can better identify the interventions that are more likely to result in positive outcomes.[6,9,24,27,66,93,136,154,164] The approach described in this text supports the importance of treatment based on presenting structural and functional impairments while respecting the pathomechanics, pathophysiology, and precautions of specific medical diagnoses.

The content of this chapter has three major emphases. The first section reviews the pathology and pathomechanics of spinal structures. The focus of the second section is on principles and guidelines for managing patients with impaired function in the spine. This section includes principles of interventions for the broad categories of acute, subacute, and chronic spinal conditions and also expands on specific interventions for impairment-based diagnostic categories. Techniques geared toward treating unique impairments are described in these sections.

The third major section contains medical diagnoses unique to the thoraco-lumbopelvic and upper thoraco-craniocervical regions. Because the function of the temporomandibular joint (TMJ) is closely related to the cervical spine, management guidelines for impairments related to the TMJ are also described. Musculoskeletal headaches can often be triggered by poor posture and cervical muscle imbalances. Thus, this chapter will conclude with a description of physical therapy interventions for patients experiencing headaches.

General therapeutic exercise techniques of intervention for all spinal and postural impairments are described in Chapter 16. Chapters 14, 15, and 16 are written with the assumption that the reader has completed or is concurrently taking a course in examination and evaluation of posture and the spine.

Spinal Pathologies and Impaired Spinal Function

The relationship of common spinal pathologies to preferred practice patterns in the *Guide to Physical Therapist Practice*[7] is outlined in Table 15.1.

TABLE 15.1 Spinal Pathologies/Surgical Procedures Related to Preferred Practice Patterns*

Pathology	Preferred Practice Patterns and Associated Impairments
■ Postural stress, strain ■ Abnormal posture	Pattern 4B—impaired posture
■ Muscle strain, tear, contusion	Pattern 4C—impaired muscle performance
■ Acute low back or cervical pain	Pattern 4E—impaired joint mobility, motor function, muscle performance, and ROM associated with localized inflammation
■ Degenerative disc disease (DDD), disc herniation ■ Degenerative joint disease (DJD), spondylosis ■ Rheumatoid arthritis ■ Radiculopathy, nerve root lesions, sciatica ■ Spinal stenosis ■ Segmental instability ■ Spondylolistheses ■ Sprains, strains	Pattern 4F—impaired joint mobility, motor function, muscle performance, ROM, and reflex integrity associated with spinal disorders
■ Laminectomy ■ Anterior cervical disc fusion (ACDF) ■ Transforaminal lumbar interbody fusion (TLIF)	Pattern 4F—Impaired joint mobility, motor function, muscle performance, range of motion, and reflex integrity associated with spinal disorders

Continued

TABLE 15.1 Spinal Pathologies/Surgical Procedures Related to Preferred Practice Patterns—cont'd

Pathology	Preferred Practice Patterns and Associated Impairments
■ Compression fracture	Pattern 4G—impaired joint mobility, muscle performance, and ROM associated with fracture
■ Spondylosis with myelopathy ■ Intervertebral disc disorders	Pattern 5H—impaired motor function, peripheral nerve integrity, and sensory integrity associated with nonprogressive disorders of the spinal cord

*Practice patterns are described in: American Physical Therapy Association: Guide to Physical Therapist Practice, ed. 2. *Phys Ther* 81:9–744, 2001.

Pathology of the Intervertebral Disc

Normal structure and function of the intervertebral (IV) disc are described in Chapter 14. Trauma, as well as normal aging can lead to degeneration of the disc and affect the mechanics of the entire spine.[61,133]

Injury and Degeneration of the Disc

Various authors have defined the terms herniation, protrusion, prolapse, and extrusion differently.[15,19,94,101,144] The following definitions are used in this text:

- Herniation: a general term used when there is any change in the shape of the annulus that causes it to bulge beyond its normal perimeter[101] (Fig. 15.1).
- Protrusion: nuclear material is contained by the outer layers of the annulus and supporting ligamentous structures.
- Prolapse: frank rupture of the nuclear material into the vertebral canal.[15,94]
- Extrusion: extension of nuclear material beyond the confines of the posterior longitudinal ligament or above and below the disc space, as detected on magnetic resonance imaging (MRI),[144] but still in contact with the disc.[101]
- Free sequestration: the extruded nucleus has separated from the disc and moved away from the prolapsed area.[101]

Fatigue Breakdown and Traumatic Rupture

A decrease in the continuity and integrity of structure of the annulus fibrosus may occur with repeated stress over time, causing fatigue breakdown or traumatic rupture.[3,4]

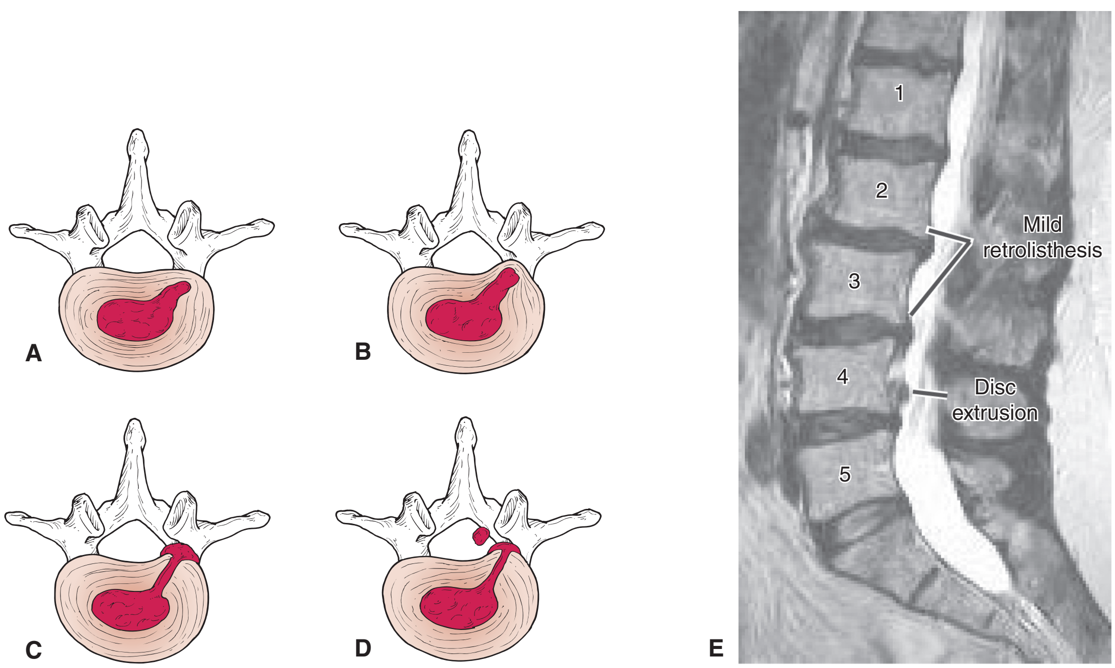

FIGURE 15.1 Disc breakdown, showing **(A)** breakdown and compression of fibrous layers of the annulus and displacement of disc material; **(B)** radial fissures/tears with nuclear material bulging against the outer annulus; **(C)** extrusion of nuclear material through the outer annulus but still in contact with the disc; **(D)** sequestration of nuclear material beyond the annulus; and **(E)** magnetic resonance imaging (MRI) scan of a 61-year-old patient with low back pain and symptoms radiating into the leg. The scan demonstrates moderate multilevel degenerative disc disease of T12–L1 through L4–5 with mild retrolisthesis of L2 on L3 and L3 on L4. At the L4–5 level, note a small diffuse disc bulge with large paracentral disc extrusion dissecting cranially.

Fatigue breakdown. Over time, the annulus breaks down as a result of repeated overloading of the spine in flexion with asymmetrical forward bending and torsional stresses.[3,4,43,88]

- With torsional stresses, the annulus becomes distorted, most obviously at the posterolateral corner opposite the direction of rotation. The layers of the outer annulus fibrosus lose their cohesion and begin to separate from each other.
- Each layer then acts as a separate barrier to the nuclear material. Eventually, radial tears occur, and there is communication of the nuclear material between the layers.[43]
- With repeated forward bending and lifting stresses, the layers of the annulus are strained. They become tightly packed together in the posterolateral corners; radial fissures develop; and the nuclear material migrates down the fissures.[3,4] Outer layers of annular fibers can contain the nuclear material so long as they remain a continuous layer.[3] After injury, there is a tendency for the nucleus to swell and distort the annulus. Distortion is more severe in the region in which the annular fibers are stretched.[4] If the outer layers rupture, nuclear material may herniate through the fissures.
- Healing is attempted, but there is poor circulation in the disc.[11] There may be self-sealing of a defect with nuclear gel or proliferation of cells of the annulus. Any fibrous repair is weaker than normal and takes a long time because of the relative avascular status of the disc.

Traumatic rupture. Rupture of the annulus can occur as a one-time event, or it can be superimposed on a disc where there has been gradual breakdown of the annular rings. This is seen most commonly in traumatic hyperflexion injuries.[4]

Axial Overload

Axial overload (compression) of the spine usually results in end-plate damage or vertebral body fracture before there is any damage to the annulus fibrosus.[16,19] Scheuermann's disease occurs when the nucleus migrates either superior or inferior through a cracked end-plate. When there is a compression fracture, flexion and axial loading usually causes increased pain. Pain may occur without nerve root involvement, although there may be referred pain in the extremities. Scheuermann's disease and compression fracture are discussed in the third section of this chapter.

Age

Individuals are most susceptible to symptomatic disc injuries between the ages of 30 and 45 years. During this time the nucleus is still capable of imbibing water, but the annulus weakens owing to fatigue loading over time and therefore is less able to withstand increased pressures when there are disproportionately high or repetitive stresses. The nuclear material may protrude into the tears of fissures, which most commonly are posterolateral and, with increased pressures, may bulge against the outer annular fibers, causing annular distortion. The nuclear material may also extrude from the disc through complete fissures in the annulus.[3,11,43,94]

Degenerative Changes

Any loss of integrity of the disc from infection, disease, herniation, or an end-plate defect becomes a stimulus for degenerative changes in the disc.[11] A strong genetic component has been linked to disc degeneration, whereas smoking and a history of heavy lifting appear to have little effect on this disease process.[10] Battie[10] identified people who were diagnosed with a disc injury prior to turning 21 and found they were four to five times more likely to have a significant family history of intervertebral disc pathologies.

- Degeneration is characterized by progressive fibrous changes in the nucleus, loss of the organization of the rings of the annulus fibrosus, and loss of cartilaginous end-plates.[11]
- As the nucleus becomes more fibrotic, it loses its capacity to imbibe fluid. Water content decreases, and there is an associated decrease in the size of the nucleus. Acute disc protrusions caused by a bulging nucleus pulposus against the annulus or extrusions of the nucleus through a torn annulus are rare in older people.
- It is possible to have protrusions of the annulus fibrosus without bulging from nuclear pressure. Myxomatous degeneration with annular protrusion has been demonstrated in disc lesions in older people.[163]

Effect on Spinal Mechanics

Injury or degeneration of the disc affects spinal mechanics in general.[126] During the early stages, there is increased mobility of the segment with greater than normal flexion/extension and forward and backward translation of the vertebral body, leading to segmental instability. Force distribution through the entire segment is altered, causing abnormal forces in the facets and supporting structures.[18,43,89]

Disc Pathologies and Related Conditions

Disc herniation, tissue fluid stasis, discogenic pain, and swelling from inflammation are conditions that may result from prolonged flexion postures, repetitive flexion microtrauma, or traumatic flexion injuries. Initially, symptoms may be exacerbated when attempting extension but then may be decreased when using carefully controlled extension motions. Several studies have documented that patients with a herniated nucleus pulposus (HNP) who have symptom reduction with an extension approach to treatment respond favorably to conservative nonsurgical treatment.[6,88]

Tissue Fluid Stasis

During sustained end-range flexed postures in the spine, the discs, facet joints, and ligaments are placed under sustained loading.[15] The intradiscal pressure increases, and there is compression loading on the cartilage of the facets and a distractive tension on the posterior longitudinal ligament

and posterior fibers of the annulus fibrosus. Ligamentous creep and fluid transfer occur. Sudden movement into extension does not allow for redistribution of the fluids and so increases the vulnerability of the distended tissue to injury and inflammation.[155] Symptoms may be similar to those described for disc lesions, because they lessen with repeated extension motions and respond to treatment described in the management section (under 'Extension Bias') later in the chapter.

Signs and Symptoms of Disc Lesions and Fluid Stasis

Etiology of Symptoms

The disc is innervated by the mixed spinal nerve and the gray ramus communicans. Since only the outer one-third of the annulus has nerve innervation,[128] not all disc protrusions are symptomatic.

Pain. Symptoms of pain arise from pressure of a swollen disc or swollen tissues against pain-sensitive structures (ligaments, dura mater, blood vessels around nerve roots) or from the chemical irritants of inflammation if there is herniated disc material.[11,135]

Neurological signs and symptoms. Neurological signs arise from pressure against the spinal cord or nerve roots. The only true neurological signs and symptoms are specific myotome weaknesses and specific dermatome sensory changes. Radiating pain in a dermatomal pattern, increased myoelectric activity in the hamstrings, decreased straight-leg raising, and depressed deep tendon reflexes can also be associated with referred pain stimuli from spinal muscles, interspinous ligaments, the disc, and facet joints and therefore are not true signs of nerve root pressure.[19,81,107]

Variability of symptoms. Symptoms are variable depending on the degree and direction of the protrusion as well as the spinal level of the lesion.

- Posterior or posterolateral protrusions are most common. With a small posterior or posterolateral lesion, there may be pressure against the posterior longitudinal ligament or against the dura mater or its extensions around the nerve roots. The patient may describe a severe midline backache or pain spreading across the back into the buttock and thigh.
- A large posterior protrusion may cause spinal cord signs such as loss of bladder control and saddle anesthesia. If a large protrusion is untreated or undiagnosed in the cervical region, it may lead to cervical myelopathy.
- A large posterolateral protrusion may cause partial cord or nerve root signs.
- An anterior protrusion may cause pressure against the anterior longitudinal ligament, resulting in back pain. There are no neurological signs.
- The most common levels of protrusion are the segments between the fourth and fifth lumbar vertebrae and between the fifth lumbar vertebra and sacrum,[95,129,130,147] although a protrusion may occur at any level, including the cervical spine. Disc herniations in the thoracic spine are extremely rare (only 1 in 1000[129,130]) due in part to the small disc to vertebrae ratio and the stable osseous anatomy of the thoracic region. They are most common at T11 and T12 because of the increased mobility in this area. Herniations in the thoracic region are much more severe, because if the disc herniates directly posterior, this will place the person at risk for spinal cord compression.

Shifting symptoms. Symptoms from a disc lesion may shift if there is integrity of the annular wall because the hydrostatic mechanism is still intact.[101,102]

Inflammation. Contents of the nucleus pulposus in the neural canal may cause an inflammatory reaction and irritate the dural sac, its nerve root sleeves, or the nerve roots. The symptoms may persist for extended periods and are not responsive to purely mechanical changes. The back pain may be worse than leg pain on the straight-leg raising test. Poor resolution of this inflammatory stimulus may lead to fibrotic reactions, nerve mobility impairments, and chronic pain.[99,140,143] Early medical intervention with anti-inflammatory agents is usually necessary.[140]

Onset and Behavior of Symptoms from Disc Lesions

Onset. Onset is usually between 20 and 55 years of age but most frequently from the mid-30s to 40s. Except in cases of trauma, symptomatic onset in the lumbar spine is usually associated simply with bending, bending and lifting, or attempting to stand up after having been in a prolonged recumbent, sitting, or forward-bent posture. The person may or may not have the sensation of something tearing.[102] Although cervical disc lesions are not as prevalent, a prolonged flexed spinal position as in a forward head posture may lead to or exacerbate symptoms from a protrusion. Many patients have a predisposing history of a faulty flexion posture.

Pain behavior. Pain may increase gradually when the person is inactive, such as when sitting or after a night's rest. The patient often describes increased pain when attempting to get out of bed in the morning or when first standing up. Symptoms are usually aggravated with activities that increase the intradiscal pressure, such as sitting, forward bending, coughing, straining, or when attempting to stand after being in a flexed position. Usually, symptoms are lessened when walking except when the bulge is large or the nuclear material has prolapsed and moved beyond the confines of the annulus.[102]

Acute pain. When there is inflammation during the acute phase, pain is almost always present but varies in intensity, depending on the person's position or activity.

When there is a lumbar disc lesion, initially discomfort is noticed in the lumbosacral or buttock region. Some patients experience aching that extends into the thigh or leg. In the

cervical spine, initially pain is noticed in the midscapular and shoulder area. Numbness or muscle weakness (neurological signs) is not noted unless the protrusion has progressed to a degree to which there is nerve root, spinal cord, or cauda equina compression.

Objective Clinical Findings in the Lumbar Spine

NOTE: The following information relates to a contained posterior or posterolateral nuclear protrusion in the lumbar spine.[102] The impairments are summarized in Box 15.1.

- The patient usually prefers standing and walking to sitting.

BOX 15.1 Summary of Common Impairments Related to Disc Protrusions in the Lumbar Spine

- Pain, muscle-guarding
- Flexed posture and deviation away from (usually) the symptomatic side
- Neurological symptoms in dermatome and possibly myotome of affected nerve roots
- Increased symptoms (peripheralization) with sitting, prolonged flexed postures, transition from sit to stand, coughing, straining
- Limited nerve mobility, such as straight-leg raising (usually between 30° and 60°)
- Peripheralization of symptoms with repeated forward-bending (spinal flexion) tests

- The patient may have a decrease in or loss of lumbar lordosis and may have some lateral shifting of the spinal column.
- Forward bending is limited. When repeating the forward-bending test, the symptoms increase or peripheralize. *Peripheralization* means the symptoms are experienced farther down the leg (Fig. 15.2).
- Backward bending is limited; when repeating the backward-bending test, the pain lessens or centralizes. *Centralization* means that the symptoms recede up the leg or become localized to the back. If the protrusion cannot be mechanically reduced, backward bending peripheralizes or increases the symptoms.
- If there is a *lateral shift* of the spinal column, backward bending increases the pain. If the lateral shift is first corrected, repeated backward bending lessens or centralizes the pain (see Figs. 15.5 and 15.6 in the management section of this chapter).
- Testing passive lumbar flexion in the supine position (double knees-to-chest) and passive extension in the prone position (press-ups) usually produces signs similar to those of the standing tests, but results may not be as dramatic because gravity is eliminated.
- Pain between 30° and 60° of straight-leg raising is considered positive for interference of dural mobility but not pathognomonic for a disc protrusion.[156]
- Contained nuclear protrusion can be influenced by movement because the hydrostatic mechanism is still intact. A complete tear of the outer layers of the annulus disrupts the hydrostatic mechanism, so the herniated or prolapsed nuclear material cannot be influenced by movement.[101] Anti-inflammatory intervention by a

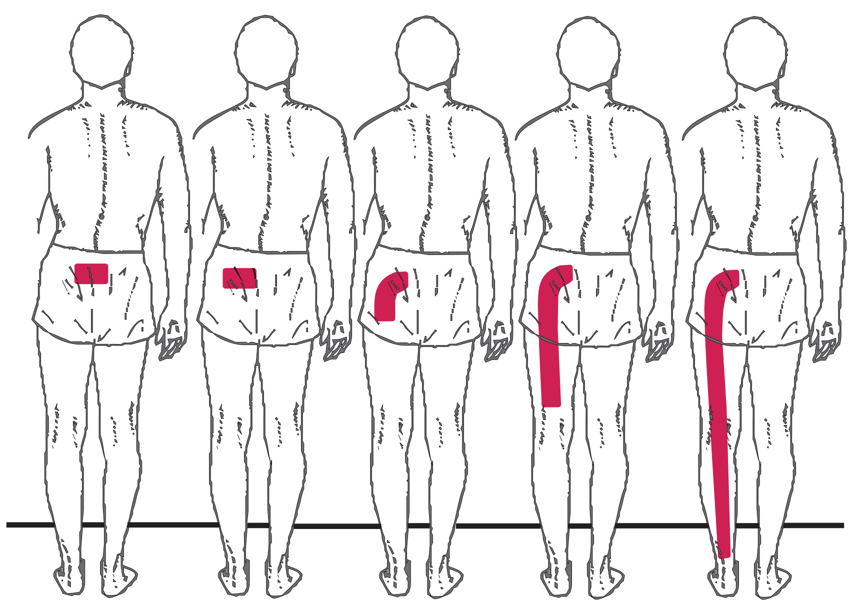

FIGURE 15.2 Examples of peripheralization and centralization of lower-quarter symptoms. Viewing the images left to right illustrates peripheralization of symptoms; from right to left illustrates centralization.

physician is important during the acute phase. Patients with disc extrusions may respond to conservative measures owing to resolution of the inflammation and resorption of the disc material.[144]

Objective Clinical Findings in the Cervical Spine

- Findings are similar to those in the lumbar spine except they are displayed in the respective dermatomes and myotomes of the cervical nerve roots.
- Initially, the patient may present with a faulty forward head posture and may hold the head in a guarded side-bent or rotated position away from the symptomatic side.
- Cervical flexion peripheralizes the symptoms; neck retractions (axial extension) followed by extension may centralize the symptoms of a contained nuclear bulge.
- There may be nerve mobility impairments in the upper extremity.
- Traction may relieve or centralize the symptoms.
- In severe cases, the patient may present with bilateral symptoms or cervical myelopathy characterized by gait abnormalities, upper motor neuron lesions, and/or leg weakness and paresthesia.

Pathomechanical Relationships of the Intervertebral (IV) Disc and Facet Joints

The disc and facets make up a three-joint complex between two adjoining vertebrae and are biomechanically interrelated. An asymmetrical disc injury affects the kinematics of the entire unit plus the joints above and below, resulting in asymmetrical movements of the facets, abnormal stresses, and eventually cartilage degeneration.[127]

Disc Degeneration

As the disc degenerates, there is a decrease in both water content and disc height. The vertebral bodies approximate, and the intervertebral foramina and spinal canal narrow.[18,19] This is called degenerative disc disease (DDD).

Initial Changes

Initially, there is increased slack with increased mobility and translation in the spinal segment. Opposition of the facet surfaces changes, and the capsules are strained, resulting in irritation, swelling, and muscle spasm.

Altered Muscle Control

Altered joint receptor function negatively affects muscle recruitment in swollen joints.[151] Pain has also been cited as a factor for altered and diminished recruitment patterns in the stabilizing muscles of the spine.[69,70,73] Increasing shear forces from poor mid-range stabilization places increased stresses on the osteoligamentous support structures, which is thought to contribute to segmental hypermobility or instability.[47]

Progressive Boney Changes

Eventually, with the repeated irritation due to the faulty mechanics, there are progressive boney changes in the facet and vertebral body margins. This is known as spondylosis, osteoarthritis (OA), or degenerative joint disease (DJD). Osteophyte formation along the facets and spondylitic lipping and spurring along the vertebral bodies occur, and hypomobility develops.[89,108] These changes lead to additional narrowing of the associated foramina and spinal canal. In the cervical spine, the uncovertebral joints thicken, roughen, and distort.[139]

Related Pathologies

Segmental (Clinical) Instability

Segmental instability has been described as poor control in the neutral zones within the physiological range of spinal movement because of a decrease in the capacity of the neuromuscular stabilizing system to control the movement.[47,127] Clinically, patients demonstrate difficulty moving in the mid-ranges of spinal motion and may demonstrate shifting or fluctuation in movement. (See section on pathomechanics of spinal instability in this chapter.)

Stenosis

Stenosis is narrowing of a passage or opening. In the spine, stenosis is any compromise of the space in the spinal canal (central stenosis), nerve root canal, or foramen (lateral stenosis); it can be congenital or acquired and can occur at any age. The narrowing may be caused by soft tissue structures, such as a disc protrusion, fibrotic scars, or joint swelling; by boney narrowing as with spondylitic osteophyte formation or spondylolisthesis; or by faulty posture. With progression, neurological symptoms develop. Extension exacerbates the symptoms.[116]

Neurological Symptoms: Radiculopathy

Spinal nerve root or spinal cord symptoms occur:

- When protrusion of the disc compresses against the cord or nerve roots.
- When there is decreased disc height due to degenerative changes[134] or excessive translation of the vertebra from shear forces resulting in decreased foraminal space. The nerve root becomes impinged between the tip of the superior articulating facet and the pedicle.
- When there is an inflammatory response due to trauma, degeneration, or disease with accompanying edema and stenosis.

- When spondylosis results in osteophytic growth on the articular facets or along the disc borders of the vertebral bodies that decreases spinal canal or intervertebral foraminal size.
- When there is spondylolisthesis or when there is scarring or adhesion formation after injury or spinal surgery.

Dysfunction

The cycle of dysfunction caused by injury, pain, and muscle splinting leads to further restriction of movement, pain, and muscle splinting unless appropriate therapy is introduced. There are additional descriptions of facet joint pathologies in the following section.

Pathology of the Zygapophyseal (Facet) Joints

Facet joints are synovial articulations that are enclosed in a capsule and supported by ligaments; they respond to trauma and arthritic changes similar to any peripheral joint.

Various types of meniscoid-like structures or invaginations of the facet capsules are present in the zygapophyseal joints of the spine. They are synovial reflections containing fat and blood vessels. In some cases, dense fibrous tissue develops as a result of mechanical stresses.[15] Some people describe entrapment of these structures between the articulating surfaces with sudden or unusual movement as a source of pain and limited motion via tension on the well-innervated capsule.[15,153] Bogduk[15] describes the *locked-back mechanism* as being "extrapment" of the meniscoids in the supracapsular or infracapsular folds, which then blocks the return to extension from the flexed position. It is called an "extrapment" because the meniscoid fails to re-enter the joint cavity; consequently, it becomes a space-occupying lesion in the capsular folds, causing pain as it impacts against and stretches the capsules.

Common Diagnoses and Impairments from Facet Joint Pathologies

The etiology of facet joint pathologies may be a result of trauma, degeneration, or a systemic disease. Box 15.2 summarizes the impairments and functional limitations.

Facet Sprain/Joint Capsule Injury

There is usually a history of trauma, such as falling or a motor vehicle accident. The joints react with effusion (swelling), limited range of motion (ROM), and accompanying muscle guarding. The swelling may cause foraminal stenosis and neurological signs.

BOX 15.2 Summary of Common Impairments and Activity Limitations (Functional Limitations) Related to Facet Joint Pathology

- *Pain*: When acute, there is pain and muscle guarding with all motions; pain when subacute and chronic is related to periods of immobility or excessive activity.
- *Impaired mobility*: Usually hypomobility and decreased joint play in affected joints; there may be hypermobility or instability during early stages.
- *Impaired posture.*
- *Impaired spinal extension:* Extension may cause or increase neurological symptoms due to foraminal stenosis; therefore, may be unable to sustain or perform repetitive extension activities without exacerbating symptoms.
- *Any functional activity that requires flexibility or prolonged repetition of trunk motions*, such as repetitive lifting and carrying of heavy objects, may exacerbate symptoms in the arthritic spine.

Spondylosis, Osteoarthritis, and Degenerative Joint Disease

Spondylosis and OA are synonymous terms. This pathology may also be referred to as DJD. Osteoarthritis involves degeneration of the IV disc as well as the facet joints. Usually, there is a history of faulty posture, prolonged immobilization after injury, or severe or repetitive trauma.

- During the early stages of degenerative changes, there is greater play, or hypermobility/instability, in the three-joint complex. Over time, stress from the altered mechanics leads to osteophyte formation with spurring and lipping along the joint margins and vertebral bodies. Progressive hypomobility with boney stenosis results. The encroachment of osteophytes on the spinal canal and intervertebral foramina may cause neurological signs, especially with spinal extension and side bending.[19]
- Usually, when there is hypomobility, compensatory hypermobility occurs in neighboring spinal segments.
- Pain with movement and/or joint stiffness following periods of rest are the primary reasons people seek physical therapy.
- Pain may result from the stresses of excessive mobility or from stretch to hypomobile structures. Pain may also be a result of the encroachment of developing osteophytes against pain-sensitive tissue or of swelling and irritation because of excessive or abnormal mobility of the segments.
- The degenerating joint is vulnerable to facet impingement, sprains, and inflammation, as is any arthritic joint.
- In some patients, movement relieves the symptoms; in others, movement irritates the joints, and painful symptoms increase.

Rheumatoid Arthritis

Symptoms of rheumatoid arthritis (RA) can affect any of the synovial joints of the spine and ribs. There is pain and swelling.

- RA in the cervical spine presents special problems. There are neurological symptoms wherever degenerative change or swelling impinges against neurological tissue. There is increased fragility of tissues affected by RA, such as osteoporosis with cyst formation, erosion of bone, and instabilities from ligamentous necrosis. Most common of the serious lesions are atlantoaxial subluxation and C4–5 and C5–6 vertebral dislocations.[106]
- Pain or neurological signs originating in the spine may or may not be related to subluxation. Therefore, these signs should be used as a precaution whenever dealing with this disease because of the potential damage to the spinal cord.[106]
- X-ray examinations are important in ruling out instabilities; signs and symptoms alone are not conclusive.

PRECAUTION: Inappropriate movements of the spine in patients with RA, such as performing cervical manipulation, could be life-threatening or extremely debilitating because of the potential to cause damage to the cervical cord or vertebral artery.[106]

Ankylosing Spondylitis (AS)

AS is a rheumatic disease characterized by chronic inflammation of the ligaments in the lumbar and spinal areas.[52] The inflamed cartilage/boney junction will fuse in approximately 20% of the population.[160]

- The prevalence of this pathology is approximately 1 to 3 per 1000 people, and the diagnosis peaks in the mid-20s.[39]
- This pathology appears to begin in the lumbar spine and progress cephalad. The sacroiliac joints are affected nearly 100% of the time, followed by the neck (75%), lumbosacral area (50%), and hips and heels (30%).[52,92]
- There is a gradual loss of motion and the person will complain of general stiffness. The patient may initially complain of bilateral pain in his or her sacroiliac joints, thoracic spine, or shoulders. The person will wake up early with pain and stiffness and have difficulty standing up straight.
- In advanced cases, radiographs will reveal a "bamboo" spine. This imaging identifies where the anterior longitudinal ligament has fused to the vertebral bodies. Decreased joint spaces may also be identified on the film.[52,92]

PRECAUTION: Atlanto-axial subluxation is the hallmark of cervical spine involvement. Extreme caution should be used when assessing and manipulating the cervical spine region to avoid causing serious or fatal injury.[52,92,158]

Facet Joint Impingement (Blocking, Fixation, Extrapment)

With a sudden or unusual movement, the meniscoid of a facet capsule may be extrapped, impinged (entrapped), or stressed, which causes pain and muscle guarding. The onset is sudden and usually involves forward bending and rotation.[15,155]

- There is loss of specific motions and attempted movement induces pain. At rest, the individual has no pain.
- There are no true neurological signs, but there may be referred pain in the related dermatome.
- Over time, stress is placed on the contralateral joint and on the disc, leading to problems in these structures.

Pathology of the Vertebrae

Axial overload (compression) of the spine may cause end plate damage or vertebral body fracture. Compression fracture is a complication of osteoporosis.

Compression Fracture Secondary to Osteoporosis

The prevalence, risk factors, prevention, recommendations for general exercise, and exercise precautions for osteoporosis are described in detail in Chapter 11. Vertebral compression fractures most often occur in the thoracolumbar region as the result of a fall or trauma or from performing basic ADLs that require forward bending of the trunk.

- Fractures usually occur during the sixth or seventh decade of life in the anterior vertebral body.
- Pain may be referred to the low back or abdominal region with or without lower extremity radiculopathy.
- Patients present with increased thoracic kyphosis (sometimes called dowager's hump) and lumbar lordosis secondary to instability, boney changes (wedging), and muscle weakness.
- Exercise prescription is based on the person's pain tolerance.
- Surgical interventions, such as vertebroplasty, may be indicated in severe cases or to prevent progression.

Scheuermann's Disease

Scheuermann's disease is a rare congenital and/or degenerative weakening of the vertebral endplates, typically seen at T10–L2.[95] The nucleus pulposus can protrude vertically into the vertebral end-plate, which can lead to a boney necrosis or Schmorl's nodes. Scheuermann's disease may also be caused by insufficient blood supply to the growing bone. This pathology is usually seen in the second decade of life and may be diagnosed as "growing pains."

Pathology of Muscle and Soft Tissue Injuries: Strains, Tears, and Contusions

Common impairments and functional limitations are summarized in Box 15.3.

BOX 15.3 Summary of Common Impairments and Activity Limitations (Functional Limitations) Associated with Muscle and Soft Tissue Injuries

Acute Stage
- Pain and muscle guarding
- Pain with contraction of the muscle or stretch on the muscle
- Interference with ADLs (rolling over, turning, sitting, sit to stand, standing, walking)

Subacute and Chronic Stages
- Impaired muscle performance
- Impaired mobility—may have contractures in muscle and related connective tissue or may have adhesions at site of tissue injury
- Impaired spinal control and stabilization during functional activities
- Impaired postural awareness
- Limited IADLs, work, and recreational activities (difficulty with repetitive or sustained postures, lifting, pushing, pulling, reaching, and holding loads)

General Symptoms from Trauma

Often more than one tissue is injured as a result of trauma. The extent of the tissue involvement may not be detectable during the acute phase.

- There is pain, localized swelling, tenderness on palpation, and protective muscle guarding regardless of whether the injured tissue is inert or contractile. Muscle guarding serves the immediate purpose of immobilizing the region. If the muscle contraction is prolonged, it results in the buildup of metabolic waste products and sluggish circulation. This altered local environment results in irritation of the free nerve endings, so the muscle continues to contract and becomes the source of additional pain (see Fig. 10.1).
- Ligamentous strains cause pain when the ligament is stressed. If torn, there is hypermobility of the segment.
- As healing of the involved structures occurs, there may be adaptive shortening or scar tissue adhering to surrounding tissue and restricting tissue mobility and postural alignment.

Common Sites of Lumbar Strain

A common site for injury in the lumbar region is along the iliac crest. This is where many forces converge around the attachment of the lateral raphe of the lumbodorsal fascia, quadratus lumborum, erector spinae, and iliolumbar ligament (see Fig. 14.12). Injury to this region frequently occurs with falls and with repeated loading of the region during lifting or twisting motions.

Common Sites of Cervical Strain

Common injuries in the neck and upper thoracic region occur with flexion/extension trauma. Serious cervical trauma may result in vertebral fractures and spinal cord injury. Discussion of vertebral fractures and spinal cord injury is beyond the scope of this text.

Extension injuries. When the head rapidly accelerates into extension, if nothing stops it (such as a headrest in a car), the occiput is stopped by the thorax. The posterior structures, especially the joints, are compressed. The anterior structures (longus colli, suprahyoid, and infrahyoid muscles) are stretched. The mandible is pulled open; the condylar head of the temporomandibular joint translates forward, stressing the joint structures; and the muscles (masseter, temporalis, medial pterygoids) controlling jaw elevation are stretched.

Flexion injuries. When the head rapidly accelerates into flexion and nothing stops it (such as the steering wheel or air bag in a car), the chin is stopped by the sternum. The mandible is forced posteriorly so the condylar head is forced into the retrodiscal pad in the joint. The posterior cervical muscles, ligaments, fasciae, and joint capsules are stretched.

Postural Strain

Strain to the posterior cervical, scapular, and upper thoracic muscles and fasciae is common with postural stresses such as prolonged sitting at a computer terminal, drawing table, or desk. Structures in the low back region are strained with faulty standing and sitting postures. Postural stresses are described in detail in Chapter 14.

Emotional Stress

Emotional stress is often expressed as increased tension in the posterior cervical or lumbar region.

Activity Limitations and Participation Restrictions

Impaired muscle function underlies most spinal problems that demonstrate pain or poor spinal control and stabilization during functional activities. When acute, muscle guarding interferes with basic activities, such as rolling over, sitting, standing, and walking, as well as ability to participate in family, work, and recreational demands. With the subacute and chronic conditions, muscle impairments result in poor stabilization and spinal control in prolonged upright postures and activities. Stability of the spine is imperative for most activities and needs to be addressed to minimize restrictions and improve function.

Pathomechanics of Spinal Instability

Spinal stability was defined and described in Chapter 14. The mechanical model of stability in which stability is maintained over the base of support by the guy wire function of the global and segmental musculature was reviewed, as was the functional model proposed by Panjabi and colleagues[124–126] in which stability is visualized as a three-legged stool that requires not only the active muscle function but also the passive osteoligamentous structures and neural control from the central nervous system to program muscle response for spinal stability. All three legs of the stool are necessary for stability; instability results when one (or more) of the legs does not function properly.

There are various grades of instability. Patients who have severe symptoms and radiographic evidence of excessive motion and who do not respond to conservative treatment become candidates for spinal fusion.[47] Surgical fusion of the cervical and lumbar regions are discussed later in this chapter. Clinical instability that can be managed by therapeutic exercise interventions is defined by an increase in the neutral zone.

Neutral Zone

The *neutral zone*[124,125] is the area that is mid-range in the ROM of a spinal segment in which no stress is placed on the passive osteoligamentous structures. In the spine, the neutral zone is relatively small (usually only several degrees of range is possible between any two vertebrae before the elastic zone of the inert tissues is reached) and is controlled by dynamic tension in the deep segmental musculature that attaches to each of the spinal segments.

The neutral zone can be visualized as a ball lying on the bottom of a bowl. The sides of the bowl represent the osteoligamentous structures that provide passive support of the spinal segment. When the ball is disturbed, it rolls back and forth and up against the sides of the bowl and eventually settles back in the middle. A deep bowl has a smaller region in which the ball can roll back and forth and therefore, less motion or more stability; a shallow bowl has a larger region in which the ball can roll, so there is greater displacement or more mobility (less stability) (Fig. 15.3 A and B). Muscles added to this visualization are depicted as bungee cords that are attached to the ball and go outward to the edges of the bowl; they help center the ball in the middle of the bowl when perturbations occur (Fig. 15.3 C). In a structure in which there is less stability (more segmental movement), the muscles have greater responsibility to maintain the neutral zone (ball in the middle of the bowl).

Neutral spine. The term neutral spine is used clinically to define the mid-range of motion.

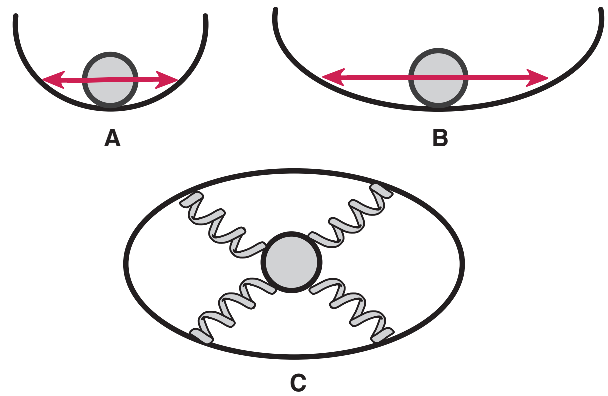

FIGURE 15.3 Neutral zone of a spinal segment depicted as a bowl, with the sides of the bowl representing the osteoligamentous tissues and the moving ball representing the segmental mobility. **(A)** In a deep bowl, when perturbations disturb the ball, there is little motion as the ball rolls back and forth and settles in the center of the bowl—representing stability. **(B)** In a shallow bowl, there is greater motion—representing greater segmental mobility or instability. **(C)** Viewing the bowl from above, bungee cords attached to the ball and the sides of the bowl represent the dynamic function of segmental muscles. Appropriately graded tension in the bungee cords stabilizes the ball when perturbations disturb the unit.

Instability

If there is an increase in the neutral zone, the segment may show signs of instability.[47,124-126] More segmental movement may occur owing to disc degeneration, spondylolysis, spondylolisthesis, or ligamentous laxity; or it may be due to poor neuromuscular control of the deep segmental stabilizing muscles in maintaining the neutral zone because of fatigue, altered recruitment pattern, reflex inhibition from pain, or some pathology.[47,125,126,157] The individual may experience neck or back pain when aberrant movement occurs at the segment or stresses are imposed at the end of the range (relaxed postures for a period of time or sudden stress that the muscles cannot control).

FOCUS ON EVIDENCE

It has been shown that activation and function in the transversus abdominis (TrA) changes (delayed and more phasic) in patients with low back pain[71,72]; there may be atrophy, structural change, and altered electromyographic (EMG) activity in the multifidus at the painful spinal level as well,[30,68,137] possibly indicating less effective stabilizing action from these muscles. Studies have also documented that training the deep segmental muscles for postural control and stability improves the long-term outcome in patient populations with acute[67] and chronic[121] low back pain as well as pelvic girdle pain following pregnancy.[152] In the cervical region, studies have documented that training the stabilizing function of the deep cervical musculature for postural control decreases the frequency and intensity of symptoms of cervical headaches.[78]

Management Guidelines Based on Stages of Recovery and Diagnostic Categories

Principles of Management for the Spine

At the time of a low back or cervical injury, impairments, activity limitations, and participation restrictions are not known. Up to 60% of acute back injuries resolve within 1 week and up to 90% resolve within 6 weeks[83] with a recurrence rate of less than 25%.[14] Disabilities are dependent on the extent of the injury. If it involves the spinal cord, levels of complete paralysis may occur. If it involves the nerve roots (also the cauda equina), varying degrees of sensory loss in specific dermatomes and muscle weakness in specific myotomes may occur, which may or may not interfere with the individual's daily personal and work-related activities. Upper-quarter nerve roots affect function of the arms and hands; lower-quarter nerve roots affect function of the lower extremities, especially during weight-bearing activities. Studies on chronic pain syndromes as a result of back injuries seem to conclude that the degree of disability is related to psychological, economic, and sociological factors and prior incidence of injury more than the actual tissues involved.[64,91] Nerve root involvement and pain provocation with active movements in several directions are more common in patients who develop chronic pain.[64] Discussion of treatment for spinal cord injuries and chronic pain syndromes is beyond the scope of this book.

Examination and Evaluation

History, systems review, and testing. A history and systems review of the patient is conducted to rule out any serious conditions, determine if the patient should be referred to another practitioner, or determine if the patient's condition is appropriate for physical therapy intervention. Then, if it is safe, tests and measures are conducted to determine if the source of symptoms can be influenced by mechanical changes in position or movement and to establish a baseline of impairment and functional limitations measurements from which changes can be documented. Examination techniques and procedures are beyond the scope of this text, but a brief summary of concerns in the spinal area is listed to help focus on critical decisions prior to establishing an intervention strategy.

- *Serious "red flag" conditions related to orthopedic conditions* that should be referred to a physician for management include spinal cord symptoms and signs (upper motor neuron lesions), recent trauma in which spinal fracture or instabilities have not been ruled out, and serious pain (especially pain that awakens the individual) that cannot be explained mechanically.
- *Psychological distress* may interfere with a patient's recovery; therefore, referral to an appropriate professional may be indicated for a multidisciplinary approach in the patient's care.
- *Neurological symptoms* should be explored in an attempt to relate them to spinal cord, nerve root, spinal nerve, plexus, or peripheral nerve patterns. Causes of nerve root signs frequently seen by physical therapists include intervertebral disc protrusions; boney, soft tissue, or vascular stenosis in the spinal canal or intervertebral foramina; facet joint swelling; and nerve root tension from restricted mobility or inflammation.
- *Pain patterns* should be explored to determine if they relate to a known musculoskeletal pattern or signal a medical condition. It should be recognized that pain is interpreted in many ways and has various meanings for different people; therefore, the information is interpreted as only one factor when determining cause of the symptoms.

Stage of recovery. Time frames for each recovery stage vary depending on the reference used. In general, the acute stage usually lasts less than 4 weeks; the subacute stage is 4 to 12 weeks; and the chronic stage is greater than 12 weeks.[2] Chronic pain syndromes generally are conditions that extend beyond 6 months.

- *Acute inflammatory stage.* The patient experiences constant pain, and there are signs of inflammation. No position or movement completely relieves the symptoms. Medical intervention with anti-inflammatory medications is usually warranted.
- *Acute stage without signs of inflammation.* Symptoms are intermittent and related to mechanical deformation. There may be signs of nerve irritability when the nerve root or spinal nerve is compressed or placed under tension. The patient may be categorized into an extension bias, a flexion bias, or a nonweight-bearing bias based on the presenting posture, movement impairments, or positions of symptom relief. These categories are described in greater detail in the next section. Delitto and associates[33] classified patients as being at this stage if they cannot stand longer than 15 minutes, sit longer than 30 minutes, or walk more than one-quarter mile without their status worsening.
- *Subacute stage.* Usually at this stage, certain movements and postures with some instrumental activities of daily living (IADLs) still provoke symptoms, such as lifting, vacuuming, gardening, and other activities requiring repetitive movement of loads, so a basic lifestyle cannot fully be resumed. A more thorough examination is conducted to identify specific activity and participation restrictions and impairments that could be interfering with recovery.
- *Chronic stage.* When this stage is reached, emphasis is placed on returning the patient to high-level demand activities

that require handling repetitive loads on a sustained basis over a prolonged period of time (from heavy material handling, to repetitive household activities that include lifting small children, to strenuous athletic activities).

Diagnosis, prognosis, and plan of care. As mentioned in the introduction to this chapter, specific pathologies and medical diagnoses often do not guide the therapist when choosing appropriate treatment interventions, and various systems of patient classification for treating musculoskeletal impairments and functional limitations are present in the literature.[2,33,34,48,101,138,145] In addition, validation studies supporting clinical prediction rules are available to assist the therapist in making decisions when developing and modifying interventions.[9,24,26,27,49,66,93,136,154] The material in the remainder of this section is organized to integrate impairment-based diagnostic categories with the medical model of spinal pathologies in order to help the therapist choose an intervention strategy that best enhances the patient's recovery. Specific medical diagnoses with unique regional features and interventions are described in the last section of this chapter.

The decisions concerning the approach to treatment are determined by the patient's responses to the examination maneuvers and the maneuvers that provide the greatest relief of symptoms. Adjustments in the intervention occur as the patient progresses through the healing process. The categories described in this and the following sections are summarized in Box 15.4.

FOCUS ON EVIDENCE

Audrey and associates[9] studied 312 acute, subacute, and chronic patients with low back pain (with or without sciatica). They found significantly greater improvement in outcomes for individuals whose exercise interventions were matched with their directional preference (flexion, extension, or side glide/rotation) than those who undertook nondirectional exercises.

Long[93] identified patients with chronic low back pain as either centralizers (peripheral symptoms lessened or became more proximal) or noncentralizers as a result of repeated movement tests. Long concluded that those who were classified as centralizers had greater improvement in outcome measures (pain rating, return to work rate) than noncentralizers.

BOX 15.4 Impairment-Based Diagnostic Categories That Direct Intervention[33,48,101,138]

General: Stage of Recovery
- Acute with inflammation (0–4 weeks).
- Acute without inflammation (0–4 weeks): intermittent symptoms with acute nerve root symptoms.
- Subacute (4–12 weeks).
- Chronic (>12 weeks).
- Chronic pain syndrome (>6 months).

Nonweight-Bearing Bias: Traction Approach
- Patient does not tolerate being upright for basic ADLs and IADLs.
- Movement testing makes symptoms worse.
- Traction (or other nonweight-bearing procedures) relieves symptoms.

Extension Bias: Extension Approach
- Patient usually presents with flexed posture—a *lateral shift* may also be present.
- Extension tests decrease or centralize symptoms.
- Diagnosis may include intervertebral disc lesions, impaired flexed posture, fluid stasis.

Flexion Bias: Flexion Approach
- Patient usually presents with flexed posture and is more comfortable when flexed.
- Extension tests exacerbate or peripheralize symptoms.
- Diagnoses may include spondylosis, stenosis, extension load injuries, swollen facet joints.

Hypermobility/Functional Instability: Stabilization/Immobilization Approach
- Patients present with hypermobile spinal segment(s); poor spinal stability (segmental or global).
- Diagnoses may include trauma, ligamentous laxity, spondylolysis, or spondylolisthesis.

Hypomobility: Mobilization/Manipulation Approach
- Restricted mobility in one or more spinal segments.

Muscle and Soft Tissue Lesions: Exercise Approach
- Patient usually presents with guarded posture or increased muscle tension.
- Diagnoses may include strains, tears, contusions, or overuse.

Postural Pain Syndrome: Exercise and Conditioning Approach
- Patient presents with faulty posture; symptoms increase with sustained position.
- Diagnoses may include postural strain, cervico-genic headache, thoracic outlet syndrome, poor physical condition
- Movement, posture correction, and exercise decrease symptoms

General Guidelines for Managing Acute Spinal Impairments: Protection Phase

Use of modalities and massage to decrease pain and swelling from acute symptoms is appropriate during the acute stage. It is also important that the patient becomes an active participant in his or her program. Kinesthetic training of neutral or functional spinal posture, nondestructive movements in the pain-free range, awareness and activation of deep segmental musculature, and basic functional training maneuvers are taught if they do not exacerbate the symptoms. Specific interventions for various impairments, specific biases, or

syndromes and common pathologies in the spinal region are described in the remaining sections of this chapter. Specific techniques for kinesthetic training, deep segmental muscle activation, stabilization training, joint manipulation, and functional training activities for the acute stage in the cervical and lumbar spinal regions are described in Chapter 16. Management guidelines for treating the patient with acute symptoms are summarized in Box 15.5. The following points are fundamental to all interventions.

Patient Education

It is important to engage patients in all aspects of intervention, including information about anticipated progress and outcome, the healing time of inflamed tissues or reduction of symptoms due to nerve root pressure (if indicated), and precautions and contraindications.

Symptom Relief or Comfort

If a patient is experiencing acute inflammation from a traumatic injury, there is constant pain; yet, often an optimal position of comfort or symptom reduction can be determined in which there is the least amount of stress on the inflamed, irritated, or swollen region. The terms functional position or functional range are used to describe this position.[109] (Neutral position is mid-range.) The functional range may change for the individual as the tissues heal and the person gains mobility and strength in the region. Some pathological conditions typically tend to cause symptoms in one portion of the range and are relieved in another range.[109] The following terms, describing subcategories of diagnoses or syndromes, have been popularized based on the work of Morgan,[109] Saal and associates,[140,142] Delitto and colleagues,[33] and Fritz and George.[48]

Extension bias-extension syndrome. The patient's symptoms are lessened in positions of extension (lordosis). Sustained flexed postures or repetitive flexion motions load the anterior disc region, causing fluid redistribution from the compressed areas and swelling and creep in the distended areas. This is frequently the mechanism of symptom production with posterior or posterolateral intervertebral disc lesions

BOX 15.5 MANAGEMENT GUIDELINES—
Acute Spinal Impairments/Protection Phase

Impairments, Activity Limitations, and Participation Restrictions (Functional Limitations)

Pain and/or neurological symptoms
Inflammation
Inability to perform ADLs and IADLs
Guarded posture (prefers flexion, extension, or nonweight-bearing)

Plan of Care	Intervention
1. Educate the patient.	1. Engage patient in all activities to learn self-management. Inform patient of anticipated progress and precautions.
2. Decrease acute symptoms.	2. Modalities, massage, traction, or mobilization/manipulation as needed. Rest only for first couple days if needed.
3. Teach awareness of neck and pelvic position and movement.	3. Kinesthetic training: cervical and scapular motions, pelvic tilts, neutral spine.
4. Demonstrate safe postures.	4. Practice positions and movement and experience effect on spine. Provide passive support/bracing if needed.
5. Initiate neuromuscular activation and control of stabilizing muscles.	5. Deep segmental muscle activation techniques: ▪ Lumbar spine: drawing-in maneuver, multifidus contraction. ▪ Cervical spine: gentle head nods Basic stabilization: with arm and leg motions (passive support if needed, progress to active control).
6. Teach safe performance of basic ADLs; progress to IADLs.	6. Roll, sit, stand, and walk with safe postures. Progress tolerance to sitting longer than 30 minutes, standing longer than 15 minutes, and walking > 1 mile.

or injury to the posterior longitudinal ligament. Whether the pathology is an injured disc or stressed and swollen tissues, repeated extension motions and positions relieve the symptoms by moving the fluid to reverse the stasis. These techniques are described in the section 'Extension Bias.' Some patients present with a lateral shift, which usually requires correction before extension relieves the symptoms.[101-103]

Flexion bias-flexion syndrome. The patient's symptoms are lessened in positions of spinal flexion and provoked in extension. This is often the case when there is compromise of the facets, intervertebral foramen, or spinal canal, as in boney spinal stenosis, spondylosis, and spondylolisthesis.

Nonweight-bearing bias-traction syndrome. The patient's symptoms are lessened when in nonweight-bearing positions, such as when lying down or in traction. Symptoms also lessen when spinal pressure is reduced by leaning on the upper extremities (using arm rests to unweight the trunk), by leaning the trunk against a support, or when in a pool. The condition is considered *gravity sensitive* because the symptoms worsen during standing, walking, running, coughing, or similar activities that increase spinal pressure. Often, traction and aquatic therapy are the only interventions that minimize symptoms during the acute phase.

Kinesthetic Awareness of Safe Postures and Effects of Movement

The patient is taught how to identify and assume the spinal position that is most comfortable and reduces the symptoms using pelvic tilts for lumbar positioning and head nods and chin tucks for cervical spine positioning. If necessary, corsets or cervical collars are used to provide support, and the patient is taught how to use passive positioning to help maintain the functional position during the acute stage (Box 15.6).

BOX 15.6 Examples of Passive Positioning of the Spine

- *Supine:* Hook-lying flexes the lumbar spine; extended legs extends the lumbar spine. A pillow under the head flexes the neck; a small roll under the neck stabilizes a mild lordosis with the head neutral.
- *Prone:* Use of a pillow under the abdomen flexes the lumbar spine; no pillow extends the spine. To maintain the cervical spine in neutral alignment without rotation, a split table or a small towel roll placed under the forehead provides space for the nose, so the patient does not turn the head.
- *Sitting*: Usually causes spinal flexion, especially if the hips and knees are flexed. To emphasize flexion, the feet are propped up on a small footstool; to emphasize extension, a lumbar pillow or towel roll is placed in the low-back region. To unweight the spine, the arms are placed on an armrest, or a reclining chair is used.
- *Standing:* Usually causes spinal extension; to emphasize flexion, one foot is placed on a small stool.

Muscle Performance: Deep Segmental Muscle Activation and Basic Stabilization

Whether the patient has a cervical or lumbar problem, as soon as tolerated, the patient is taught how to activate the deep segmental muscles.

Lumbar Region: Deep Segmental Muscle Activation

For the lumbar region, the "*drawing-in*" maneuver is used to activate the transversus abdominis and a gentle bulging contraction of the multifidus muscle. Facilitation techniques, which are described in detail in the 'Segmental Activation' section of Chapter 16, may be necessary.

Cervical Region: Deep Segmental Muscle Activation

For the patient with cervical pain, gentle head nods and slight flattening of the cervical lordosis in the supine position are used for activation of the longus colli and multifidus.

Basic Stabilization

Once the patient learns to activate the segmental muscles, simple upper and lower extremity motions with the spine stabilized are added to the intervention to initiate training of the global stabilizers. *Passive prepositioning* is used if the patient is unable actively to maintain his or her functional position, as described in Box 15.6. For both cervical and lumbar problems, the patient is instructed first to do the drawing-in maneuver followed by gentle arm motions within a range that does not exacerbate symptoms. Leg motions require greater lumbopelvic control and are introduced if the patient is able to demonstrate pelvic control and the symptoms are not exacerbated with the movements. Suggestions for determining the exercise progressions are detailed in the 'Stabilization' section of Chapter 16.

Basic Functional Movements

The patient is taught to perform simple movements for ADLs while protecting the spine in the functional position. These movements include rolling from prone to supine and reverse, lying to sitting and reverse, sitting to standing and reverse, and walking. Descriptions of these maneuvers are in the 'Functional Activities' section of Chapter 16.

PRECAUTIONS: Review any special precautions for the condition with the patient. Condition-specific precautions are described in the remaining sections of this chapter.

General Guidelines for Managing Subacute Spinal Impairments: Controlled Motion Phase

When the signs and symptoms of the inflammatory process are under control and pain is no longer constant, the patient is progressed through a program of safe muscle endurance and strengthening exercises to prepare the tissue for functional activities and rehabilitation training. Functional activities that can be performed safely are resumed. Pain may still interfere with some daily activities, but it should no longer be constant. Poor neuromuscular control and stabilization, poor

postural awareness and body mechanics, decreased flexibility and strength, and generalized deconditioning may be the underlying impairments at this stage. Intervention during this stage is critical, because either the patient feels good and tends to overdo activities and reinjures the tissues, or the patient is fearful and does not adequately resume safe movements, leading to further participations restrictions. Either extreme may slow down the recovery process.

Management guidelines for cervical and lumbar problems that require controlled motion interventions are summarized in Box 15.7. The specific techniques and progressions of intervention outlined here are described in detail in Chapter 16.

Pain Modulation

At this stage, use of modalities to modulate pain is not recommended. Emphasis is placed on increasing patient awareness of posture, strength, mobility, and spinal control and their relationship to modulating pain.

Kinesthetic Training

Kinesthetic training is progressed by using reinforcement techniques. Feed-forward control of the deep segmental musculature, active control of the spinal position, and correct posture are reinforced in a variety of ways until activation and control become habitual. Kinesthetic training overlaps the stabilization exercises.

Stretching/Manipulation

Decreased flexibility in joints, muscles, and fascia may restrict the patient's ability to assume normal spinal alignment. Manual techniques and safe self-stretching techniques are used to increase muscle, joint, and connective tissue mobility.

BOX 15.7 MANAGEMENT GUIDELINES—Subacute Spinal Problems/Controlled Motion Phase

Impairments, Activity and Participation Restrictions (Functional Limitations)

Pain: only when excessive stress is placed on vulnerable tissues
Impaired posture/postural awareness
Impaired mobility
Impaired muscle performance: poor neuromuscular control of stabilizing muscles; decreased muscle endurance and strength
General deconditioning
Inability to perform IADLs for extended periods of time
Poor body mechanics

Plan of Care	Intervention
1. Educate the patient in self-management and how to decrease episodes of pain.	1. Engage patient in all activities emphasizing safe movement and postures. Home exercise program. Ergonomic adaptation of work or home environment.
2. Progress awareness and control of spinal alignment.	2. Practice active spinal control in pain-free positions and with all exercises and activities. Practice posture correction.
3. Increase mobility in restricted muscles/joint/fascia/nerve.	3. Joint mobilization/manipulation, neuromobilization, muscle inhibition, self-stretching.
4. Teach techniques to develop neuromuscular control, strength, and endurance.	4. Progress stabilization exercises; increase repetitions (emphasize muscle endurance). Initiate extremity-strengthening exercises in conjunction with spinal stabilization.
5. Develop cardiopulmonary endurance.	5. Low to moderate intensity aerobic exercises; emphasize spinal bias.
6. Teach techniques of stress relief/relaxation.	6. Relaxation exercises and postural stress relief.
7. Teach safe body mechanics and functional adaptations.	7. Practice stable spine lifting, pushing/pulling, and reaching. Practice activities specific to desired outcome emphasizing spinal control, endurance, and timing.

Muscle Performance

Exercises are progressed with increased challenges for control, muscular endurance, and strength in the spinal stabilizing muscles; these exercises include activities that increase control and strength in the extremity musculature in conjunction with spinal stabilization. If a patient continues to display a flexion or extension bias, exercises are adapted to emphasize that particular bias and prevent stresses in the symptom-producing direction.

- Stabilization exercises are used to emphasize movement and resistance to the extremities while maintaining control of the spinal position. Increasing the time and number of repetitions builds muscle endurance at each level of performance.
- Wall slides, partial squats, partial lunges, pushing, and pulling against resistance are used to strengthen the extremities to prepare for lifting, reaching, pushing, and pulling activities.
- When the patient learns effective spinal control with the stabilizing muscles in a variety of stabilization exercise routines, dynamic trunk and neck strengthening exercises, such as curl-ups, back extension, and cervical motions, are introduced. Care is taken to monitor symptoms and modify any activities that exacerbate the problem.

Cardiopulmonary Conditioning

Aerobic capacity is usually compromised after injury. It is important to guide the patient in the initiation of or safe return to an aerobic conditioning program. It may be necessary to help the patient identify activities that do not exacerbate spinal symptoms.

Postural Stress Management and Relaxation Exercises

It is common that a patient's symptoms are exacerbated with sustained postural stresses such as sitting at a computer, talking on the phone (head tilted), or repetitive forward bending (shoe salesman); therefore, analysis of work, home, or recreational postures and activities is a necessary component of the patient's program. The patient is then advised about methods to correct the sustained or repetitive postural stresses. In addition, frequent changes of position and movement through the pain-free ROMs should be encouraged. It may be necessary to teach the patient how to consciously relax tension in muscles to relieve stress. Relaxation exercises are described in Chapter 14.

Functional Activities

Once the patient has learned spinal control and stabilization and has developed adequate flexibility and strength for specific tasks, components of the task are incorporated into the exercise program and then into the patient's daily lifestyle. Safe body mechanics are included in all aspects of care.

General Guidelines for Managing Chronic Spinal Impairments: Return to Function Phase

Patients who have been treated through the acute and subacute phases of healing with appropriately graded exercises should have minimal structural or functional impairments that prevent or restrict daily activities. Individuals who must do heavy material handling (e.g., a manual laborer, firefighter, caregiver of small children or patients) or who participate in high-demand sports activities may require additional rehabilitative training to return safely to these high-demand activities and to avoid further injury. Impairments in strength, endurance, neuromuscular control, and skill are related to the functional goals of the individual. At this stage, conditioning and spinal control during high-intensity and repetitive activities are emphasized. Any underlying impairments that interfere with the desired outcomes must be remediated. Management guidelines for return to function are summarized in Box 15.8. Suggestions for progressing exercise intervention techniques from the subacute through chronic stages are described in Chapter 16.

Management Guidelines: Nonweight-Bearing Bias

During examination, some patients do not respond to extension, flexion, or even mid-range spinal positions or motions due to the acuity of or mechanical stimuli from their condition. The person is often more comfortable lying down and may have partial or full relief with a traction test maneuver to the painful region of the spine.

For these patients, use of traction procedures or unweighting the body in a pool may be the interventions of choice until the symptoms stabilize.

Management of Acute Symptoms

Traction

Various references have reported the benefits of traction.[19,131,147]

- Traction has the mechanical benefit of temporarily separating the vertebrae, causing mechanical sliding of the facet joints in the spine, and increasing the size of the intervertebral foramina. If done intermittently, this motion may help reduce circulatory congestion and relieve pressure on the dura, blood vessels, and nerve roots in the intervertebral foramina. Improving circulation also may help decrease the concentration of noxious chemical irritants due to swelling and inflammation.
- There may be a neurophysiological response via stimulation of the mechanoreceptors that may modulate the transmission of nociceptive stimuli at the spinal cord or brain stem level.

BOX 15.8 MANAGEMENT GUIDELINES—
Chronic Spinal Problems/Return to Function Phase

Impairments, Activity Limitations, and Participation Restrictions (Functional Limitations)

Pain: only when excessive stress is placed on vulnerable tissues in repetitive or sustained nature for prolonged periods
Poor neuromuscular control and endurance in high-intensity or destabilized situations
Flexibility and strength imbalances
Generalized deconditioning
Inability to perform high-intensity physical demands for extended periods of time

Plan of Care	Intervention
1. Emphasize spinal control in high-intensity and repetitive activities.	1. Practice active spinal control in various transitional activities that challenge balance.
2. Increase mobility in restricted muscles/joints/ fascia/nerve.	2. Joint mobilization/manipulation, neuromobilization, muscle inhibition, self-stretching.
3. Improve muscle performance; dynamic trunk and extremity strength, coordination, and endurance.	3. Progress dynamic trunk and extremity resistance exercises emphasizing functional goals.
4. Increase cardiopulmonary endurance.	4. Progress intensity of aerobic exercises.
5. Emphasize habitual use of techniques of stress relief/ relaxation and posture correction.	5. Motions and postures to relieve stress. Apply any ergonomic changes to work/home environment.
6. Teach safe progression to high-level/high-intensity activities.	6. Progressive practice using activity-specific training consistent with desired functional outcome, emphasizing spinal control, endurance, balance, agility, timing, and speed.
7. Teach healthy exercise habits for self-maintenance.	7. Engage patient in all activities and educate as to benefits of maintaining fitness level and safe body mechanics.

Harness

Various unloading devices or body weight support systems may be used, such as partially suspending the patient in a harness while he or she performs ambulation on a treadmill or gentle extremity exercises.

Pool

If a person is not fearful of being in a pool, supporting the individual with a buoyant life belt in deep water reduces the effects of gravity on the lumbar spine. If symptoms are reduced, it may be possible to begin and progress gentle stabilization exercises in this buoyant environment to meet some of the goals during the acute and subacute phases. Exercises can also be progressed by using the properties of water for resistance and stretching (see description of aquatic exercises in Chapter 9).

Progression

As healing occurs, the patient should begin to tolerate weight bearing. After re-examination and assessment, identify the impairments and activity and participation restrictions. If a bias toward flexion or extension is determined, or if there are areas of hyper- or hypomobility, plan the interventions accordingly.

Management Guidelines: Extension Bias

Patients with an extension bias often assume a flexed posture or a flexed posture with lateral deviation of the trunk or neck, but during the examination, sustained or repetitive extension maneuvers reduce or relieve their symptoms. These patients would benefit from early interventions that emphasize extension of the involved segments. The impairments may be due to a contained intervertebral disc lesion, fluid stasis, a flexion injury, or muscle imbalances from a faulty flexed posture. McKenzie[101–103] developed a method of categorizing these patients based on the extent of their pain and/or neurological symptoms. He also described the phenomena of peripheralization and centralization that accompany an expanding and

receding lesion, frequently attributed to intervertebral disc lesions (see Fig. 15.2).

Many of the techniques that were originally described by McKenzie[101-103] to manage a patient with an acute disc lesion have been found to be beneficial in the management of patients who have a cluster of signs and symptoms that categorize them into the extension bias (extension syndrome) category.[46,48,93,142]

Principles of Management

Because patients with signs and symptoms of a bulging intervertebral disc often fit into the "extension bias" category, a brief discussion of the response of the intervertebral disc is presented here.

Effects of Postural Changes on Intervertebral Disc Pressure

Relative changes in posture and activities affect intradiscal pressure. When compared to the level of pressure when standing, intradiscal pressure is least when lying supine, increases by almost 50% while sitting with hips and knees flexed, and almost doubles if leaning forward while sitting.[147] Sitting with a back rest inclination of 120° and lumbar support 5 cm in depth provides the lowest load to the disc while sitting.[7] Therefore, sitting with the hips and knees flexed or leaning forward should be avoided when there is an acute disc lesion. If sitting is necessary, there should be support for the lumbar spine by reclining the trunk 120°.

Effects of Bed Rest on the Intervertebral Disc

When a person is lying down, compression forces to the disc are reduced; and with time, the nucleus potentially can absorb more water to equalize pressures (imbibition). When lying down with the spine in flexion, the imbibed fluid accumulates posteriorly in the disc where there is greater space. Then, upon rising, body weight compresses the disc with the increased fluid, and intradiscal pressure greatly increases. The pain or symptoms from a disc protrusion are accentuated. To avoid exacerbating symptoms, absolute bed rest during the acute phase should be avoided. Bed rest during the first 2 days (when symptoms are highly irritable) may be needed to promote early healing, but it should be interspersed with short intervals of standing, walking, and appropriately controlled movement.[161]

Effects of Traction on the Intervertebral Disc

Traction may relieve symptoms from a disc protrusion. It is proposed that separating the vertebral bodies may have the effect of placing tension on the annular fibers and posterior longitudinal ligament, thus have a flattening effect on the bulge; or it may decrease the intradiscal pressure.[147] If traction relieves symptoms, the time of application must be short because with the reduced pressure fluid imbibition may occur to equalize the pressure. Then, when the traction is released, the pressure increases and symptoms are exacerbated.

Effects of Flexion and Extension on the Intervertebral Disc and Fluid Stasis

Rest in a slightly forward-bent position often lessens pain because of the space potential for the nucleus pulposus of the intervertebral disc. The patient may also deviate laterally to minimize pressure against a nerve root. Movement into extension initially causes increased symptoms. With acute disc lesions in which there is protective lateral shifting and lumbar flexion, techniques that cause lateral shifting of the spine opposite to the deviation followed by passive spinal extension (sustained or repetitive) to compress the protrusion mechanically have been found to relieve the clinical signs and symptoms in many patients.[88,102]

Patients experiencing pain due to fluid stasis after being in a sustained flexed posture also experience relief with movement into extension.

FOCUS ON EVIDENCE

In a study of 20 subjects with low back pain who were candidates for extension-based treatment, those who experienced an immediate decrease in pain intensity (N = 10) of at least 2/10 after treatment (posterior to anterior mobilization followed by prone press-ups) demonstrated a mean increase in diffusion coefficient of 4.2% of the nuclear region of the L5-S1 IV disc measured by MRI. Those who did not experience pain reduction (N=10) did not have a change in diffusion (mean decrease of 1.6% (P<.005).[11a]

Effects of Isometric and Dynamic Exercise

Isometric activities (resisted pelvic tilt exercises, straining, Valsalva maneuver) and active back flexion or extension exercises increase intradiscal pressures above normal. They, therefore, must be avoided during the acute stage of a disc lesion. Strong muscle contractions also exacerbate symptoms if a muscle has been injured. Therefore, active and resistive extension exercises are avoided during the acute stage.

Effects of Muscle Guarding

Reflex muscle guarding or splinting often accompanies an acute disc lesion and adds to the compressive forces on the disc. Modalities and gentle oscillatory traction to the spine may help decrease the splinting.

Indications, Precautions, and Contraindications for Interventions: Extension Approach

Indications. Extension is used if pain and/or neurological symptoms centralize (decrease or move more proximally) during repeated extension testing maneuvers and peripheralize (worsen) during flexion.[82,101] Extension is also indicated for flexed postural dysfunctions with limited range

into extension. If no test movements decrease the symptoms, this mechanical approach to treatment should not be used.

PRECAUTION: A patient with acute pain in the spinal region that is not influenced by changing the patient's position or by movement must be screened by a physician for signs of serious pathology.

CONTRAINDICATIONS: When there is an acute disc lesion, any form of exercise or activity that increases intradiscal pressure, such as the Valsalva maneuver, active trunk flexion, or trunk rotation, is contraindicated during the protection phase of treatment. Any movement that peripheralizes the symptoms signals a movement that is contraindicated during the acute and early subacute period of treatment. Peripheralization with extension motions may indicate stenosis, a large lateral disc protrusion, or pathology in a posterior element[141] (Box 15.9).

Interventions Using an Extension Approach in the Lumbar Spine

Management of Acute Symptoms

If symptoms are severe, bed rest is indicated with short periods of walking at regular intervals. Walking usually promotes lumbar extension and stimulates fluid mechanics to help reduce swelling in the disc or connective tissues. If the patient cannot stand upright, he or she should use crutches to help relieve the increased pressure of the forward-bent posture.[82]

If repeated flexion test movements increase the symptoms and if repeated extension test movements decrease or centralize the symptoms, all flexion activities should be avoided during the early phases of intervention. Treatment begins with the following maneuvers.

Extension

Patient position and procedure: Prone. If the flexion posture is severe, place pillows under the abdomen for support. Gradually increase the amount of extension by removing the pillows and then progress by having the patient prop himself or herself up on the elbows, allowing the pelvis to sag (Fig. 15.4 A). When propping, pillows placed under the thorax help take strain off the shoulders. Wait 5 to 10 minutes between each increment of extension to allow reduction of the water content and the size of the bulge. There should be an accompanying centralization of or decrease in symptoms. Progress to having the patient prop himself or herself up on the hands, allowing the pelvis to sag (Fig. 15.4 B).

If the sustained position of prone propping is not well tolerated, have the patient perform passive lumbar extension intermittently by repeating the *prone press-ups* (same end position as Fig. 15.4 B) rather than just propping up.

PRECAUTION: Carefully monitor the patient's symptoms. They should lessen peripherally (i.e., decreased foot and leg symptoms or decreased thigh and buttock symptoms) but may increase (centralize) in the low back. If the symptoms progress down the lower extremity (peripheralize), immediately stop the exercises and reassess.[102]

Lateral Shift Correction

If the patient has lateral shifting of the spine (Fig. 15.5), extension alone cannot reduce a nuclear protrusion of the disc until the shift is corrected. Once the shift is corrected, the patient must extend (as described above) to maintain the correction. Methods to correct the shift in various positions include the following.

Patient position and procedure: Standing with flexed elbow against the side of the deviated rib cage. Stand on the side to

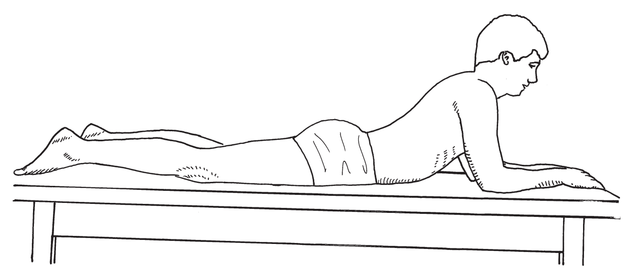
BOX 15.9 Contraindications to Specific Spinal Movements

Extension of the spine is contraindicated[64,65]:

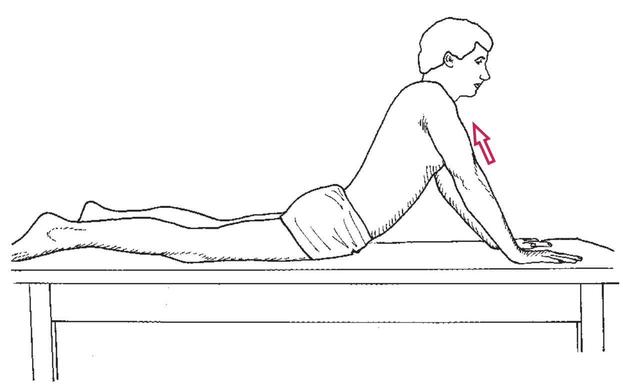
- When no position or movement decreases or centralizes the described pain
- When saddle anesthesia and/or bladder weakness is present (could indicate spinal cord or cauda equina lesion)
- When a patient is in such extreme pain that he or she rigidly holds the body immobile with any attempted correction

Flexion of the spine should be avoided:

- When extension relieves the symptoms
- When flexion movements increase the pain or peripheralize the symptoms



A



B

FIGURE 15.4 Lumbar extension is accomplished **(A)** by having the patient prop up on the elbows and **(B)** by propping on hands and allowing the pelvis to sag.

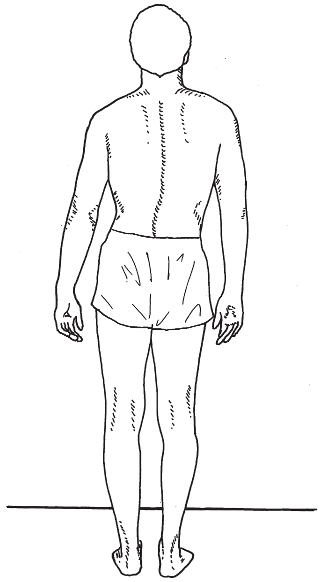


FIGURE 15.5 Patient with lateral shift of the thoracic cage toward the right. The pelvis is shifted toward the left.

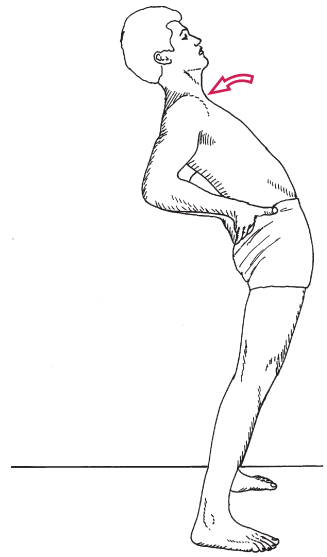

FIGURE 15.7 Standing back bend.

which the thorax is shifted and place your shoulder against the patient's elbow. Then wrap your arms around the patient's pelvis on the opposite side and simultaneously pull the pelvis toward you while pushing the patient's thorax away (Fig. 15.6). This is a gradual maneuver. Continue with the lateral shifting if centralization of the symptoms occurs. If there is overcorrection, the pain and lateral shift may move to the contralateral side, which is corrected by shifting the thorax back. The purpose is to centralize the pain and correct the lateral shift. Once the shift is corrected, *immediately* have the patient backward-bend (Fig. 15.7). Again, allow time. Progress to passive extension with prone propping and prone press-ups as previously described.

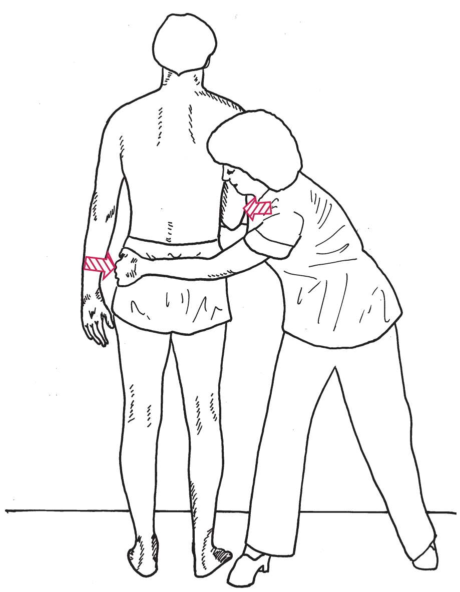

FIGURE 15.6 A lateral gliding technique used to correct a lateral shift of the thorax is applied against the patient's elbow and thoracic cage as the pelvis is pulled in the opposite direction.

Patient position and procedure: Side-lying on the side to which the thorax is shifted. Place a small pillow or towel roll under the thorax. The patient remains in this position until the pain centralizes; he or she then rolls prone and begins passive extension with prone propping and prone press-ups.

Patient position and procedure: Prone. Attempt to side-glide the thorax and pelvis toward the midline with manual pressure. The forces are in equal and opposite directions. Once the symptoms centralize, instruct the patient to begin passive extension with prone propping and prone press-ups.

Teach self-correction of the lateral shift. The patient places the hand on the side of the shifted rib cage on the lateral aspect of the rib cage and places the other hand over the crest of the opposite ilium and then gradually pushes these regions toward the midline and holds (Fig. 15.8).

Patient Education

- Help the patient recognize what positions and motions increase or decrease the pain or other symptoms by performing them under supervision.
- Instruct the patient to repeat the extension activities frequently, with lateral shift correction if necessary, during the first couple of days. The more severe the symptoms the more frequently the extension exercises should be completed. Typically they should be performed immediately upon waking up and after periods of prolonged sitting and/or bending.
- Caution the patient to stop the activity immediately if the pain worsens or peripheralizes during exercises.
- Instruct the patient to maintain an extended posture with passive support while the lesion is healing. For example, have the patient use a towel roll or lumbar pillow while sitting. This is especially important when riding in a car or sitting in a soft chair. When going to bed, have the patient pin a towel, folded lengthwise four times, around the waist.

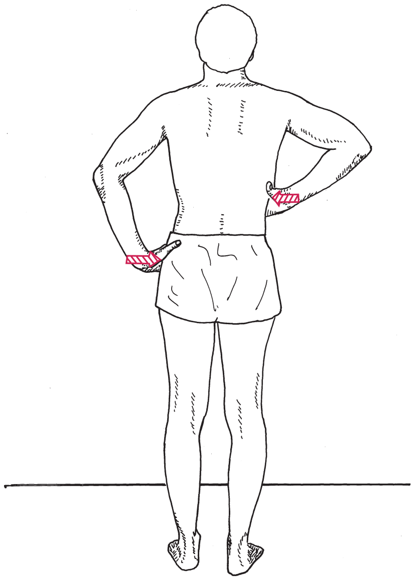

FIGURE 15.8 Self-correction of a lateral shift.

- Instruct the patient to avoid flexion activities, lifting, or any other functions that increase intradiscal pressure while symptoms are acute.
- Teach safe movement patterns to protect the back as described in the guidelines for treating acute spinal problems (see Box 15.5).

Lumbar Traction

Traction may be tolerated by the patient during the acute stage and has the benefit of widening the disc space and possibly reducing the nuclear protrusion by decreasing the pressure on the disc or by placing tension on the posterior longitudinal ligament.[147]

- Time of the traction should be short; osmotic forces soon equalize. However, upon release of the traction force, there could be an increase in disc pressure, leading to increased pain. Use less than 15 minutes of intermittent traction or less than 10 minutes of sustained traction.
- High poundage; more than half the patient's body weight is necessary for separating the lumbar vertebrae.
- If there is complete relief initially, often there is an exacerbation of symptoms later.

Joint Manipulation

Grades I through IV joint mobilization/manipulation may be utilized preceding the prone press ups, but high-velocity thrust should not be performed as this may promote inflammation at the segment. High-velocity thrusts also require a rotation component, and this may place further stress on the disc.

Kinesthetic Training, Stabilization, and Basic Functional Activities

Once the patient learns to control the symptoms the following should be emphasized.

- Teach simple spinal movements in pain-free ranges using gentle pelvic tilts. The patient is taught to be aware of how far forward and backward he or she can rock the pelvis and move the spine without increasing the symptoms. The pelvic rocking is done in supine, sitting, hand-knee all-fours (quadruped), prone-lying, side-lying, and standing positions. It is important to stay within the patient's ability to control the symptoms. *Instruct the patient to finish all exercise routines with the pelvis tilted anteriorly and the spine in extension.*
- Teach the patient basic stabilization techniques utilizing the core trunk muscles while maintaining control of the extended spinal position and performing simple extremity motions. It is important to caution against holding the breath and causing the Valsalva maneuver, which would excessively increase the intradiscal pressure.
- Encourage activities, such as walking or swimming, within the tolerance of the individual.
- Initiate passive, straight-leg raising with intermittent dorsiflexion and plantarflexion to maintain mobility in the nerve roots of the lumbar spine.

Management When Acute Symptoms Have Stabilized

Signs of Improvement

Improvement is noted with loss of spinal deformity, increased motion in the back, and negative dural mobility signs.[82] Loss of back pain with an increase in true neurological signs is an indication of worsening. The patient is tested to determine that the symptoms have stabilized; this is accomplished by performing repeated flexion and extension tests with the patient standing and then lying supine and prone as done initially. The tests may be positive for structural impairments (restricted motion, weakness, tension), but should not cause peripheralization of the symptoms, as when the condition was acute.[102]

Intervention

The emphases during this stage are *recovery of function, development of a healthy back care plan,* and *teaching the patient how to prevent recurrences* (see Boxes 15.6 and 7). The pain from adaptive shortening decreases as normal flexibility, neural mobility, strength, and endurance are restored.

In addition to general exercise instruction, teach the patient these principles.

- Following any flexion exercises, perform extension exercises, such as prone press-ups or standing back extension (see Figs. 15.4 and 15.7).
- If being in a prolonged flexed posture is necessary, interrupt the flexion with backward bending at least once every hour. Also, perform intermittent pelvic tilts.
- If symptoms of a protrusion develop and are felt, immediately perform press-ups in the prone position, anterior pelvic tilts in the quadruped position, or backward bending while standing to prevent progression of the symptoms.

Interventions to Manage a Disc Lesion in the Cervical Spine

Disc lesions in the cervical spine are less common than in the lumbar spine. Herniated discs are most common between the C6 and C7 vertebrae; this is likely due to the increased mobility at this transitional section between the cervical lordosis to the thoracic kyphosis. It may also be the result of degeneration, osteophytes, or poor posture. Patients may present with peripheral neuropathy and forward-head posture without a diagnosis of disc pathology. Symptoms increase with activities and postures that increase flexion in the lower cervical and upper thoracic spine and decrease with extension in that region (axial extension or neck retraction).[1]

Conservative management is similar to that in the lumbar spine and follows the same principles described in the previous section. Medical management includes pharmacological pain and inflammation control measures. Often disc extrusions are an indication for surgery because of potential compromise of the spinal canal and pressure on the spinal cord.[144] These procedures are described in the next section.

Acute Phase

Passive Axial Extension (Cervical Retraction)

Patient position and procedure: Begin with the patient supine, with no pillow under the head or neck. Gently nod the patient's head, and allow the neck to flatten against the treatment table. If the neck is deviated or rotated to one side, moving the head and neck back toward the midline must be done first. This may require gentle, progressive positioning and may take 10 to 20 minutes to accomplish.

Progression: Progress the retraction to hyperextension of the cervical spine and then progress to rotation. Use caution and carefully monitor the signs and symptoms; do not progress if symptoms peripheralize down the arm.

Patient Education

Teach the patient to retract his or her head and neck passively in the sitting position. The patient may gently push against the chin (caution not to push so hard as to cause joint compression of the temporomandibular joint) to direct the motion. This technique has been shown to improve the H-reflex amplitude and may be useful for improving mobility and decreasing symptoms of radiculopathy by decompressing nerve roots in the lower cervical spine.[1]

Traction

Cervical traction may relieve the patient's symptoms. As described for lumbar traction, during the acute phase, sustained traction should be no longer than 10 minutes and intermittent traction no longer than 15 minutes in duration. The dosage is at an intensity that causes vertebral separation (at least 15 lb).

Kinesthetic Training for Posture Correction

Instruct the patient in safe mechanics for maintaining the head position. During the acute phase, the patient may need to wear a cervical collar to immobilize the spine. It is important to help the patient identify the posture that centralizes the symptoms and to adjust the collar to maintain that position.

Progression as Symptoms Stabilize

Follow the guidelines described in Boxes 15.5 and 15.7. Faulty cervical, thoracic, and scapular posture may be present. Emphasize kinesthetic training for postural awareness, stabilization exercises for postural control with emphasis on the scapular and shoulder muscles, environmental adaptations to reduce postural stresses, and functional activities with safe spinal mechanics.

FOCUS ON EVIDENCE

Kjellman and Oberg[84] randomly placed 77 people with neck pain into one of the following three groups: general exercise, McKenzie extension exercise, and a control group (ultrasound and education). Outcome measures were pain intensity and the Neck Disability Index. After 12 months, all groups showed significant improvement with no significant difference between the three groups, with nearly 70% of patients reporting they were better or completely restored. The authors did note, though, that in the short term (during the first 3 weeks of treatment), those in the extension exercise group had more favorable response to treatment than the general exercise group or the control group, and there was a tendency that those in the extension exercise group used the health-care system less frequently during the 6 to 12 month period. Analysis showed significant improvement between the extension exercise group and control group at 3 weeks and at 6 months ($P<0.05$).

Disc Lesions: Surgery and Postoperative Management

Indications for Surgery

Patients with upper or lower extremity radiculopathy, caused by nerve root irritation and who have failed conservative measures including physical therapy, medications, and steroid injections may be appropriate surgical candidates.[20-22,50,85,97,123,132,159]

Common Surgeries

The two most common surgical procedures in the spine are laminectomy and fusion of one of more vertebrae.[98]

Laminectomy. A laminectomy is the removal of the lamina. A partial or hemi-laminectomy is a removal of only part of the lamina; a complete laminectomy is the excision of the entire lamina, the spinous process, and the ligamentum flavum that attached to the lamina. The primary disadvantage

to a complete laminectomy is that the surgical segment loses its anatomical stabilization.[21,22,65] A laminectomy is typically indicated over a fusion in patients with a small unilateral disc protrusion. The benefits of a laminectomy are that the patients retain segmental mobility while experiencing symptom relief.

Fusions. Fusions are indicated when the patient presents with axial pain combined with instability, severe arthritic degenerative changes, or peripheral pain that is not controlled.[20,22,50,63,85,97,123,132,159] The advantages of a spinal fusion are that it reduces or eliminates segmental motion, reduces mechanical stress at the degenerated disc area, and reduces the incidence of additional herniations at the affected disc site.[159] However, effects of a fusion may expedite the degenerative processes, create a hypermobility at adjacent spinal segments, and alter overall spinal mechanics.[12,41,65]

Procedures

Anterior cervical disc fusion. Anterior cervical disc fusion (ACDF) involves a horizontal incision at the level(s) of the cervical vertebrae that are to be fused. Both the platysma and longus coli muscles are interrupted during this procedure. Once the disc is excised, the adjacent vertebrae are then internally fixated with a single unilateral plate and screws attaching directly to the vertebral bodies. Although complications are rare, they can include sore throat, hoarseness, and difficulty swallowing.[53] Medical complications involving the heart, lungs, and other organs affect approximately 5% of surgical patients following ACDF.[98] Neurological or more serious complications, including myelopathy, radiculomyelopathy, and recurrent laryngeal nerve palsy, have been reported as ranging from 1% to 4% of the post-surgical population.[13,20,45]

Outcomes

Pain has been reported to significantly decrease following ACDF.[50,85,123] Good to excellent outcomes have been reported as high as 92%.[65]

Transforaminal lumbar interbody fusion. Transforaminal lumbar interbody fusion (TLIF) involves a vertical incision centrally along the posterior spine.[63] The paraspinals muscles, including the multifidi, are refracted prior to the removal of the lamina, spinous process, and ligamentum flavum. The vertebrae are fused together using bone from the facetetomy and autologous bone from the iliac crest.[63] Complications, occurring in 2% to 4% of patients, include infection, epidural bleeding, neural injury, postsurgical instability, epidural fibrosis, and arachnoiditis.[12,58,132]

Outcomes

Good overall outcomes of approximately 80% have been reported.[8,58] Berg and associates[12] identified that 84% of people reported improvement and/or complete resolution of pain at 1 year postoperatively and 86% at 2 years. The authors also reported that 71% of people returned to work after one year.[12]

In a similar study, Schizas and colleagues[148] reported a 2.2 point decrease in pain on the visual analogue scale and a 27 point improvement in the Oswestry Disability Index at 24 months postoperative.

Laminectomy. Laminectomies can be performed in either the lumbar or cervical spine regions. Both involve a posterior approach and are performed similarly to a posterior fusion with the exception that the vertebrae are not internally fixated to each other. The recovery time and return to work time are usually much quicker as compared with a fusion. However, similar rehabilitation guidelines are followed as described in the next section.

Postoperative Management

Postoperative management is similar for all of these surgical procedures.

Maximum Protection Phase

- *Patient education*. Educate the patient on the expectations of the surgeon, the surgical procedure, and the rehabilitation involved in the process. Also, instruct the patient on any restrictions as detailed by the surgeon. These restrictions typically include no heavy lifting (> 10 pounds) for up to 3 months. Limitations in active motions may also be imposed depending on the surgeon's preference and type of procedure.
- *Wound management and pain control*. Teach the patient to look for signs of inflammation such as redness, swelling, or non-closure of the wound.
- *Bed mobility*. The patient must relearn how to perform bed mobility as they may be wearing a spinal orthotic that prevents normal movement.
- *Bracing*. To promote healing, patients who have undergone either an ACDF or TLIF are typically placed in a Philadelphia collar then a soft collar or a chairback brace, respectively, for up to 3 months. The patient may be allowed to remove the brace to shower but must immediately don the orthotic upon getting dressed.
- *Exercises*. Encourage walking and gentle exercises that can be completed in the supine position. Include A-AROM or AROM heel slides, short-arc quads, quad and gluteal isometrics, and ankle pumps. Patients who have undergone a laminectomy are instructed to avoid excessive extension due to the weakened boney neural arch.

CONTRAINDICATIONS: Patients are to avoid a shower or getting the incision wet until it is completely closed. This is usually 1 to 2 weeks following surgery. As described above, the patient is instructed to follow the surgeon's guidelines regarding limitations with movement and lifting.

Moderate and Minimum Protection Phases

- *Scar tissue mobilization*. After the incision site is healed, initiate scar mobilization to improve connective tissue mobility and decrease pain at the surgical site.

- *Progressive stretching and joint mobilization/manipulation of restricted tissue*. Gentle (grade I to II) joint techniques at adjacent segments are indicated for pain modulation and improved ROM.
- *Muscle performance*
  - Initiate segmental and progress to global stabilization exercises to patient tolerance.[64a]
  - Address patient goals directed at minimizing specific activity restrictions and impairments.
  - Begin with single plane exercises and progress complexity as patient tolerates.
- *Gait training*. Once the patient is allowed to ambulate, an assistive device is usually indicated to facilitate an erect posture and unload some of the stress to the surgical area.

CONTRAINDICATIONS:
- The patient must continue to follow the surgeon's contraindications to promote optimal healing.
- Joint manipulations at the level(s) of the fusion are contraindicated.
- Extension exercises, including prone press-up, are contraindicated in patients who have undergone a laminectomy.

FOCUS ON EVIDENCE

A Cochrane Review of randomized, controlled studies of rehabilitation programs following lumbar disc surgery concluded that for exercise programs that started 4 to 6 weeks after surgery there was less short-term pain and disability compared to patients who received no treatment. The review also indicated high-intensity programs resulted in less short-term pain and disability than low-intensity programs, and that home exercise programs were as effective as supervised programs. None of the studies reviewed reported an increase in the reoperation rate.[120]

Management Guidelines: Flexion Bias

Patients may present with a flexed posture and be unable to extend because of increased neurological symptoms and decreased mobility; these patients would benefit from early interventions that emphasize flexion of the involved segments to relieve symptoms. The patients may have a medical diagnosis of spondylosis or spinal stenosis (central or lateral), an extension load injury, or capsular impingement or swollen facet joints, so symptoms increase with extension. The flexed position reduces or relieves the symptoms.

Principles of Management

Physical therapy interventions focus on increasing the diameter of the foramen and minimizing nerve root irritation.

Effect of position. Flexion widens the intervertebral foramina, whereas extension decreases the size of the foramina. Any compromise of the foraminal opening, such as encroachment from boney spurs or lipping or swollen tissue, reduces the space. The patient may describe intermittent nerve root symptoms (intermittent numbness or tingling) whenever the involved segment extends, indicating mechanical compression. Constant nerve root symptoms could be caused by inflammation and swollen tissue.

Effect of traction. Traction has been demonstrated to widen the intervertebral foramina. Positioning the spine in flexion prior to the application of traction provides the greatest increased space.[19,93,131] Positional traction, in which the patient is placed in side bending away from the side or direction of pain and rotation toward the pain, may also be beneficial to increase the diameter of the lateral foramen.

Effect of trauma and repetitive irritation. Swelling in the facet joints from macrotrauma or microtrauma leads to a compromised foraminal space. With degeneration and increased mobility in a spinal segment, instability could be the cause of repetitive microtrauma, leading to swelling and pain.

Effect of meniscoid tissue. The meniscoid tissue of the joint capsule may become impinged with sudden movements. This blocks specific movements, such as extension and side bending to the involved side. Manipulation and traction usually relieve the symptoms.

Indications and Contraindications for Intervention: Flexion Approach

Indications. Flexion is used if neurological and/or pain symptoms are eased with flexion and worsened with extension positions or motions.

CONTRAINDICATIONS: Extension and extension with rotation positions, motions, and exercises are contraindicated if neurological symptoms or pain worsen with these motions. Flexion exercises are contraindicated if neurological or pain symptoms peripheralize with flexion or repeated flexion maneuvers (see Box 15.9).

Techniques Utilizing a Flexion Approach

In general, spinal flexion postures and exercises are taught following the guidelines described in Boxes 15.5, 15.7, and 15.8. The following suggestions should also be considered for special conditions.

Management of Acute Symptoms

Rest and Support

- With acute joint symptoms, a cervical collar or lumbar corset may help provide rest to the inflamed or swollen facet joints or provide caution to others, so they avoid

inadvertently provoking spinal movement. It is important to discontinue the use of such devices as the acute symptoms decrease, so the muscles can learn dynamic control and avoid dependence.

- Support is also beneficial in the management of patients with RA or other disorders associated with hypermobility or instability.

Functional Position for Comfort

- For flexion bias in the lumbar spine, the position is usually with the hips and knees flexed so the lumbar spine flexes.
- In the cervical spine, the position is toward axial extension (upper cervical flexion) with some flexion also in the lower cervical region.
- If there are neurological signs, the position provides maximal opening of the intervertebral foramina to minimize impingement of the nerve root.

Cervical Traction

- Gentle intermittent joint distraction and gliding techniques may inhibit painful muscle responses and provide synovial fluid movement in the joint for healing.
- Dosages must be very gentle (grade I or II) to avoid stretching the capsules and are best applied with manual techniques during the acute stage.
- With spondylosis or stenosis, if a patient does not have signs of acute joint inflammation but does have signs of nerve root irritation, stronger traction forces may be beneficial to cause opening of the intervertebral foramina, which helps relieve the pressure.

CONTRAINDICATION: If a patient has RA, traction and joint mobilizations/manipulations in the spine are potentially dangerous because of ligamentous necrosis and vertebral instability; therefore, they should not be performed.[106]

Correction of Lateral Shift

If the patient has a lateral shift of the thoracic region along with symptom relief when in flexion, he or she may be taught self-correction.

Patient position and procedure: Standing with the leg opposite the shift on a chair so the hip is in about 90° of flexion. The leg on the side of the lateral shift is kept extended. Have the patient then flex the trunk onto the raised thigh and apply pressure by pulling on the ankle (Fig. 15.9).

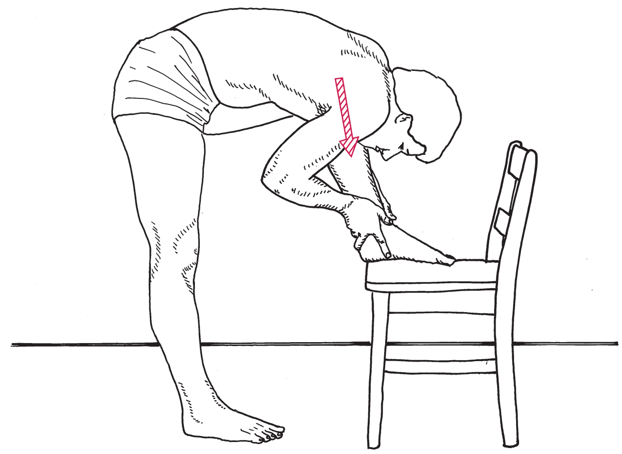

FIGURE 15.9 Self-correction of a lateral shift when there is deviation of the trunk as it flexes.

Correction of Meniscoid Impingements

If there is entrapped synovial or meniscoid tissue in a facet joint that blocks motion into extension, release of the trapped meniscoid relieves the pain and the accompanying muscle guarding. The joint surfaces need to be separated and the joint capsules made taut.[15] General techniques include traction and manipulation.

- Traction to the spine may be applied manually or mechanically. The patient also can be taught self-traction and positional traction techniques. Traction applied longitudinally along the axis of the spine has the effect of sliding the facets' joint surfaces and thus placing tension on the facet capsules. Traction with contralateral side bending and rotation of the spine has the effect of distracting the facet joint surfaces as well as placing tension on the capsules.
- Techniques of manual traction, self-traction, positional traction with rotation and manipulations are described in the stretching section of Chapter 16.

Management When Acute Symptoms Have Stabilized

General guidelines for subacute and chronic spinal problems are summarized in Boxes 15.7 and 15.8. Specific emphasis when treating patients with mobility impairments due to hypomobile or hypermobile facet joints should include the following.

- Hypomobile joints require stretching but not if the techniques stress a hypermobile region. Traction techniques may be effective if the hypermobile region is stabilized during stretching. For those trained in joint mobilization/manipulation techniques, these techniques are effective for selective facet joint stretching and have been found to be an effective part of a total treatment approach when there is instability in specific areas and restricted mobility in neighboring facet joints.[119] Emphasis is on developing dynamic stability through muscle control in the hypermobile regions while gaining mobility in the restricted regions.
- Strength and flexibility of the trunk, hip, and shoulder girdle musculature require selective stretching and strengthening. These are summarized in Box 15.10.
- If there are boney changes and osteophytic spurs, the patient should avoid postures and activities of hyperextension, such as reaching or looking overhead for prolonged periods of time. Adaptations in the environment might include using a stepstool so reaching is at shoulder level. Postures and motions emphasizing flexion of the spine that increase the size of the intervertebral foramina are usually preferred.
- For patients with RA, emphasis is on stabilization and control. Because of the potential instabilities from necrotic tissue and bone erosion, subluxations and dislocations may

BOX 15.10 Muscle Imbalances Common with Flexion Bias (Syndrome)

Lumbopelvic Region
Restricted mobility:
- Hip flexors, extensors, and external rotators

Muscle weakness:
- Abdominals
- Hip abductors

Cervicothoracic Region
Restricted mobility:
- Muscles of the anterior chest and shoulder girdle

Muscle weakness:
- Muscles of the posterior scapulothoracic region including scapular stabilizers

cause damage to the spinal cord or vascular supply and can be extremely debilitating or life-threatening.

FOCUS ON EVIDENCE

Cleland and associates[27] identified 96 consecutive patients with cervical radiculopathy. Patients had a 90% success rate using an intervention manual therapy, traction, and deep neck flexor strengthening exercises if they met the following criteria: <54 years old; dominant hand not affected; looking down does not worsen the symptoms; and muscle energy and/or thrust, traction, and deep neck flexor muscle strengthening used ≥50% of the time during PT sessions.

Tseng[154] followed 100 patients with neck pain and identified 6 variables for patient success with manipulation. The authors concluded that if the patients met four of the following criteria their chance for success using cervical manipulation was 89%. The variables are: initial Neck Disability index <11.5; bilateral involvement pattern; not performing sedentary work >5 hours each day; feeling better while moving neck; did not feel worse with neck extension; and diagnosis of spondylosis without radiculopathy.

Raney and colleagues [136] applied mechanical traction to 68 patients with neck pain for 15 minutes each session. Mechanical traction was found to be 90% successful in 90% of the patients if they met 4 of the 5 following criteria: (1) patient reported peripheralization with C4–7 mobility testing; (2) patient had a positive abduction sign; (3) patient was age 55 years or older; (4) patient returned a positive median nerve tension test; and (5) patient experienced relief of symptoms with manual distraction.

Management Guidelines: Stabilization

Patients with segmental instability—including hypermobility; ligamentous laxity; diagnoses such as spondylolysis, spondylolisthesis, or poor neuromuscular control of the deep segmental and global stabilizing musculature—require interventions that improve stability. Some of the patients may have a history of trauma, repeated manipulations, or early signs of spondylosis. Mobility testing of the spinal segments reveals increased mobility at one or more segments. There may be decreased activity in the stabilizing musculature, particularly in response to postural perturbations, and there may be faulty respiratory patterns. (Additional information on spondylolisthesis is in the final section of this chapter.)

Identification of Clinical Instability

Stress radiographs are typically used by the medical profession to identify instability. Those with more than 4 mm of translation or 10° of rotation are considered candidates for surgery.[47] Radiographs can identify problems only in the passive structures. To identify impairments in the musculature and the ability to control movement, techniques have been developed that specifically address core muscle activation and endurance and global muscle stabilization. The following may be used.

- *Quality of movement.* Observe spinal ROM (standing) and note if there is a catch or aberrant movement. Patients may demonstrate difficulty moving smoothly in the mid-ranges as well as a shifting or fluctuation in movement.[49]
- *Control of deep segmental musculature.* In the lumbar region, it is possible to palpate the transversus abdominis and multifidus muscles while the patient attempts to contract them. Devices to measure activation, such as using a biopressure feedback unit or ultrasound imaging, have been developed for both research and clinical usage[74] (see next section under 'Principles of Management' as well as Chapter 16).
- *Control of the global musculature.* Several protocols have been developed to test the stabilizing function of the global musculature.[51,62,137] They primarily challenge the isometric holding capability of the anterior, posterior, and lateral trunk musculature under various loads.

Principles of Management

Passive Support

Braces or corsets may be necessary for external support to provide stability and reduce pain.[47] Ideally, these devices should be used in conjunction with training the deep segmental musculature for dynamic control.

Deep Segmental Muscle Activation

Activation of segmental musculature may not be automatic in patients with pain or instability. In addition to verbal and tactile cues, techniques used to instruct patients include use of a biofeedback pressure cuff (Chattanooga®) and ultrasound imaging. Ultrasound imaging is primarily used in research settings because of the cost of the units. The pressure cuff has been shown to have clinical relevance in providing immediate feedback to patients.[74] Use of the cuff for testing and instruction in deep segmental muscle activation of the cervical and

lumbar regions is described in detail in the Muscle Performance section of Chapter 16.

Once the patient learns to activate the segmental muscles, emphasis is placed on sustaining the contraction over a period of time and on increasing the repetitions of the static hold to reinforce the postural function. These contractions are of low-intensity to minimize the compressive activity of the global muscles.[55]

Lumbar Region

Initially, the patient is taught to find and maintain a neutral spinal position using pelvic tilts (mid-range). The patient is then instructed in the "drawing-in maneuver" to activate the transversus abdominis, and he or she learns to contract the multifidus by bulging out the muscle. Gentle co-activation of the muscles of the perineum facilitates contraction of these segmental muscles.[114]

FOCUS ON EVIDENCE

Hicks and associates[66] determined that the patients most likely to benefit from stabilization exercises were those with lumbar segmental instability who met three or more of the following criteria: positive prone instability test, aberrant motions during lumbar ROM, average straight-leg raise less than 91°, and age less than 40 years.

Cervical Region

The patient is taught to activate the segmental musculature with gentle capital nodding and slight flattening of the cervical lordosis.[55]

Progression of Stabilization Exercises

- Progressing from segmental muscle activation to general stabilization exercises using the global musculature emphasizes cervical and pelvic control while superimposing extremity motions. Included are weight-bearing activities, such as wall slides, partial lunges, and partial squats, with emphasis on the "drawing-in" maneuver and spinal control in the neutral spinal position while doing the activities.
- Functional activities are incorporated into the stabilization exercise routines. The patient is encouraged to activate the segmental musculature consciously and maintain a neutral spinal position until it becomes habitual.

Management Guidelines: Mobilization/Manipulation

NOTE: The terms *manipulation* and *mobilization* are currently being used interchangeably, with a trend toward using the term *manipulation* (see Chapter 5). The authors of this chapter are using *manipulation* to mean graded oscillation techniques and *high-velocity thrust (HVT)* to mean high-velocity, small-amplitude motion performed at the end of the pathological limit of the joint. When describing or documenting manipulation techniques used, the clinician is reminded to define the intensity (grade I–IV or HVT) as well as spinal level (target), direction of force application, and patient position.

Some patients benefit from spinal manipulation during the early stages of intervention.[25,28] Hypomobile spinal segments may add to stress of hypermobile segments and require a combined approach of manipulation as well as stabilization exercises.[75,119] Manipulation techniques for the cervical, thoracic, and lumbar spines are described in Chapter 16.

Management: Lumbar Spine

Following determination of a hypomobile segment in the lumbar spine, perform the general manipulation (using the lumbar roll technique) up to two times followed by instruction in ROM exercises. This is repeated for two sessions, after which the patient is instructed in stabilization exercises and progressed through treatment as summarized in Boxes 15.7 and 15.8.

The lumbopelvic technique used in validation studies[24,25] as well as an alternate technique[28] are described in Chapter 16. The traction procedures described in the nonweight-bearing section earlier in this chapter may also be beneficial.

FOCUS ON EVIDENCE

In a randomized controlled trial of 71 subjects with low back pain, Flynn and associates[44] determined that patients most likely to benefit from spinal manipulation prior to stabilization exercises were those who met four of five of the following criteria: symptom duration less than 16 days; no symptoms distal to the knee; score less than 19 on a fear-avoidance measure; at least one hypomobile lumbar segment; and at least one hip with more than 35° internal rotation. This was validated by Childs and colleagues[24] in a multicenter randomized, controlled trial of 131 consecutive patients.

Fritz and associates[49] reported that those who had positive tests for spinal hypomobility had more successful outcomes if manipulation was included in the interventions; and those with hypermobility were more successful if stabilization was included.

Management: Cervical Spine

Cervical manipulation, in combination with exercise, has been shown to significantly decrease neck pain[42,59] as well as increase ROM, upper extremity and neck strength, and endurance.[17] Gross and associates[59] completed a Cochrane review and identified strong evidence in favor of manipulation combined with exercise to decrease pain when compared with a control group. While the risk of serious or life-threatening injuries has been reported from 1 in 20,000 to 5 in 10 million,[60] it is recommended that non-thrust techniques be used due to the potential risk of adverse effects, including a vertebrobasilar artery stroke.[35,76]

It is important that the thoracic spine is assessed in patients with cervical impairments.[77,87] Not only does the thoracic spine move during cervical motion, but it is prone to mobility impairments. In addition, there are common muscle attachments in both regions. Performing joint manipulation and high-velocity thrust of the thoracic spine often improves outcomes in patients with cervical complaints.[26,27,77,87]

FOCUS ON EVIDENCE

Cleland and Childs[26] performed thoracic manipulation, exercise, and patient education for 78 patients with neck pain. An 86% success rate was found for patients with three or more of the following criteria: symptoms <30 days; no symptoms distal to the shoulder, cervical extension does not aggravate the symptoms; Fear-Avoidance Belief Questionnaire-Physical Activity Score of <12; diminished upper thoracic kyphosis (T3–5); and cervical extension <30°.

Management Guidelines: Soft Tissue Injuries

As previously described, symptoms in soft tissues, including muscles, can occur as a result of direct trauma (tears/contusions), strain from sustained or repetitive activities, or as a protective mechanism (guarding/spasm) from injury to joints or other tissues. General guidelines for management follow those presented previously and are summarized in Boxes 15.4, 15.7, and 15.8. In addition, specific considerations when treating muscle injury are described in this section.

Management During the Acute Stage: Protection Phase

Pain and Inflammation Control

Use appropriate modalities and myofascial release techniques to control pain and inflammation. Passive support may be necessary to relieve the muscles from the job of supporting or controlling the injured part.

Cervical Region

Cervical collars provide passive support in the cervical region. The length of time a collar is worn during the day relates to the severity of the injury and the amount of protection required.

PRECAUTION: Collars often place the neck in a forward-head posture. This causes healing in a faulty position, which leads to future postural problems or painful syndromes. Usually, turning the collar around or cutting down the portion under the mandible allows the neck to assume correct alignment. Cervical collars are usually reserved for severe and acute whiplash injuries or postoperative intervention per the physician's recommendations.

Lumbar Region

Corsets provide passive support of the lumbar region. As with the cervical region, the length of time that a corset is worn should be related to the amount of protection required. Some patients tend to become dependent on the corset and continue to wear it even after healing when it no longer serves its intended purpose. After healing, it is better to strengthen the body's natural corset (deep abdominal muscles) and develop effective spinal mechanics (see Chapter 16).

Muscle Function

When evaluating muscle function, identify the functional position in which the patient has a decrease in the intensity of symptoms. With a muscle injury, this is often with the muscle in its shortened position. In this position, begin gentle muscle-setting techniques. Dosage is critical; resistance is minimal. Use only enough to generate a setting contraction.

Cervical Region

Patient position and procedure: Supine. Stand at the head of the treatment table, supporting the patient's head with your hands. Start with the guarding muscle in its shortened position. Ask the patient to hold as you apply gentle resistance (light enough to barely move a feather). Both the contraction and the relaxation should be gradual. There should be no neck movement or jerky resistance.

- If there has been muscle injury, the technique is repeated with the muscle kept in the shortened range for several days before beginning to lengthen it.
- As the muscle heals or if there is no muscle injury, progress the treatment by gradually lengthening the guarding muscle after each contraction and relaxation. Movement is performed only within the patient's pain-free range; no stretching is performed when there is muscle guarding.

(*Reverse muscle action.* These exercises are valuable for gentle muscle performance activity when neck motions cause pain and muscle guarding. The neck is not moved, but the muscles are called on to contract and relax. The motions include active scapular elevation, depression, adduction, and rotation. If symptoms are not exacerbated, active shoulder flexion, extension, abduction, adduction, and rotation are used to stimulate the stabilizing function of the cervical musculature.)

Lumbar Region

Patient position and procedure: Prone, with arms resting at the side. Have the patient lift the head. This initiates a setting (stabilizing) contraction of the lumbar erector spinae muscles. A stronger contraction of the lumbar extensor muscles occurs if the head and thorax are extended. Alternate hip extension also causes a setting contraction of the lumbar extensor muscles.

- When there is muscle injury, the muscle is kept in this shortened range for several days.
- For progression as the muscle heals or if there is no muscle injury, gradually allow the muscle to elongate after each contraction by putting a pillow under the abdomen and

having the patient extend the thorax on the lumbar spine through a greater range. Elongation is performed only within tolerance during the early healing phase. There should be no increase in symptoms.

Alternate position and procedure: Supine. Have the patient press the head and neck into the bed, causing a setting contraction of the spinal extensors.

Traction

Gentle oscillating traction may reflexively inhibit the pain and help maintain synovial fluid and joint-play motion during the acute stage when the muscles do not allow full ROM. Gentle techniques are most effectively applied using manual traction. Position the part with the injured tissue in a shortened position and use a dosage less than that which causes vertebral separation.

PRECAUTION: Traction techniques may aggravate a muscle or soft tissue injury if the tissue is placed in a lengthened position during the setup or with a high dosage of pull during treatment.[110]

Environmental Adaptation

If there are activities or postures that caused the trauma or are continuing to provoke symptoms, identify the mechanism and modify the activity or environment to eliminate the potential of recurrence of the problem.

Management in the Subacute and Chronic Stages of Healing: Controlled Motion and Return to Function Phases

Once acute symptoms are under control, re-examine the patient and determine the impairments and functional limitations. Refer to the general guidelines for management as presented in Boxes 15.7 and 15.8.

Management of Regional Diagnoses

Most spinal pathologies may affect any region in the spine and tend to cluster in the diagnostic categories that are described in the previous section. There are several pathologies unique to the thoracic and lumbopelvic region and several unique to the craniocervical and upper thoracic region; the interventions for these pathologies are described in this section. Table 15.2 summarizes the interventions for the spinal and related pathologies described in this text.

TABLE 15.2 Summary of Interventions for Spinal and Related Pathologies

Pathology	Diagnostic Category	Intervention Summary
Osteoarthritis (OA), Degenerative Joint Disease (DJD), Spondylosis. *Stenosis (central or lateral), myelopathy, radiculopathy, and/or radicular pain, may be confounding pathologies from joint swelling and/or spurring and lipping*	Flexion Bias	▪ Posture education ▪ Flexion approach ▪ Segmental and global trunk stabilization ▪ Mobilization/manipulation as needed ▪ Nerve glides if indicated ***Cervicothoracic region:*** ▪ Cervical and scapular stabilization ▪ Flexibility to anterior thorax, anterior shoulder girdle, upper cervical spine ***Lumbopelvic region*** ▪ Flexibility to anterior trunk and hips
Herniated Disc *DJD, stenosis (central or lateral), myelopathy, radiculopathy, and/or radicular pain, may be confounding pathologies*	Extension Bias	▪ Posture education ▪ Extension approach ▪ Segmental and global stabilization ▪ Mobilization/manipulation as needed ▪ Nerve glides if indicated **CONTRAINDICATION:** HVT ***Lumbar Region:*** ▪ Side-glide if necessary; prone press-ups, back extension ▪ LE and trunk stretching as needed

TABLE 15.2 Summary of Interventions for Spinal and Related Pathologies—cont'd

Pathology	Diagnostic Category	Intervention Summary
		Cervical Region: ■ Chin tucks ■ Scapular stabilization ■ UE and cervical stretching
Scoliosis *In severe cases will have compromise of cardiorespiratory systems*	Variable, depending on region of scoliosis and impairments	■ Posture education ■ Stretch side of concavity ■ Strengthen side of convexity ■ Segmental and global stabilization ■ Scapular stabilization ■ Mobilization/manipulation as needed
Compression fracture from osteoporosis	Extension Bias	■ Posture education ■ Extension approach ■ Segmental and global trunk stabilization ■ Scapular stabilization ■ Hip stretching as needed ■ Weight-bearing activities and exercises ■ Bed mobility as needed ■ Mobilization/manipulation as needed **CONTRAINDICATIONS:** HVT and aggressive joint manipulation; abdominal crunches (trunk flexion)
Scheuermann's disease	Extension Bias	■ Posture education ■ Extension approach ■ Segmental and global stabilization exercises ■ LE and trunk stretching as needed ■ Mobilization/manipulation as needed ■ Nerve glides if indicated **CONTRAINDICATIONS:** HVT
Postural Pain Syndrome	Postural strain, poor physical condition	■ Posture education ■ Ergonomic assessment and adaptations as needed ■ Segmental and global stabilization exercises ■ Extremity and trunk stretching as needed ■ Conditioning exercises ■ Relaxation exercises
Spondylolisthesis	Flexion Bias	■ Posture education ■ Flexion approach ■ Segmental and global stabilization ■ LE and trunk stretching as needed ■ Mobilization/manipulation as needed **CONTRAINDICATIONS:** Exaggerated extension manipulation and stretching
Ankylosing Spondylitis	Extension Bias	■ Posture education ■ Extension approach ■ Exaggerate lumbar lordosis ■ Segmental and global stabilization

Continued

TABLE 15.2 Summary of Interventions for Spinal and Related Pathologies—cont'd

Pathology	Diagnostic Category	Intervention Summary
		■ LE and trunk stretching as needed ■ Mobilization/manipulation as needed **CONTRAINDICAITONS:** Manipulation at ankylosed segments
Sacroiliac joint (SIJ) Sprain/Pain		■ Posture education ■ Segmental and global stabilization ■ LE and trunk stretching as indicated ■ Mobilization/manipulation and/or ME techniques as needed ■ Nerve glides if indicated
Rib Subluxation		■ Posture education ■ Scapular stabilization ■ UE and cervical stretching ■ Mobilization/manipulation as needed
Suboccipital Hypomobility *Assess vertebral artery for tolerance to joint mobilization/manipulation and ME techniques*		■ Posture education ■ Scapular stabilization ■ UE and cervical stretching ■ Mobilization/manipulation as needed ■ Muscle energy to improve ROM
Tension Headaches *Assess vertebral artery for tolerance to joint mobilization/manipulation and ME techniques*	Upper cervical flexion bias; lower cervical extension bias	■ Posture education ■ Upper cervical flexion approach; lower cervical extension approach ■ Cervical and scapular stabilization ■ UE, cervical, and suboccipital stretching ■ Mobilization/manipulation as needed ■ ME techniques to improve ROM ■ Stress management
Temporomandibular joint (TMJ)/facial pain *Cervical pain and mobility impairments may be confounding variables*	Postural	■ Posture education ■ Jaw posture education ■ TMJ mobilization/manipulation ■ Suboccipital interventions ■ Mandibular and tongue proprioception exercises

Lower Thoracic and Lumbopelvic Region

Compression Fracture Secondary to Osteoporosis

As described earlier in this chapter, compression fractures of the vertebral bodies, secondary to osteoporosis, commonly occur in the thoracolumbar region as a result of axial loading or trunk flexion. Symptoms are provoked with flexion activities.

Interventions

- Teach stabilization exercises to promote a neutral thoracolumbar junction and develop spinal stability.
- Teach scapular stabilization exercises to assist with correct posture and decrease the progression of a thoracic kyphosis, commonly seen in people with osteoporosis.
- Stretch the antagonist muscles. These muscles include the shoulder horizontal adductors, internal rotators, hip flexors, and internal rotators.
- Instruct in correct lifting techniques and advise to avoid extreme and prolonged trunk flexion when possible.
- Whenever possible, instruct patients who have osteoporosis in preventative measures and safe exercises as summarized in Box 15.11.

CONTRAINDICATIONS: Avoid trunk flexion activities and exercises, such as bending forward to lift heavy objects and performing toe touch and sit up exercises.

Spondylolisthesis

Spondylolisthesis is defined as an anterior slippage of one vertebra on the one directly below it. It is graded according to the amount the superior vertebra moves in relation to the one directly below it as identified on a radiograph. Grade I includes

BOX 15.11 Preventative Measures for Patients with Osteoporosis

- Emphasize correct posture (thoracic extension and scapular stabilization).
- Avoid high impact activities and exercises (running, jumping, high-impact aerobics and sports).
- Avoid exercises and activities that emphasize trunk flexion, or that could easily cause one to loose their balance.
- Perform safe balance and weight-bearing exercises (walking, stairclimbing).

all films that demonstrate up to a 25% slippage; grade II is reserved for patients who have a slippage from 26% to 50%; grade III indicates a 51% to 75% slip; and grade IV is more than 75% slippage.[57,162] This pathology can occur at any age and is associated with instability at the involved segment. Spondylolisthesis can be the result of either a congenital malformation in the pars interarticularis, a traumatic fracture of the vertebral arch, or degenerative changes associated with age or obesity.

Physical Therapy Interventions

- Use the flexion approach described in the previous section.
- Stabilization exercises: include both segmental and global stabilization.
- Stretch the hip flexors.
- Gentle manipulations (grades I and II) for pain modulation. Avoid high-velocity thrust techniques, as they may further exacerbate the symptoms or instability.

Ankylosing Spondylitis

This is a rheumatic disorder that results in the eventual ossification of the both the anterior and posterior longitudinal spinal ligaments and the facet joints. Ankylosing spondylitis first appears in adolescence and "peaks" in the mid-20s.[52,92,158,160] People with this pathology complain of pain at the bilateral sacroiliac joints, thoracic or lumbar spine, shoulder, or foot regions.

Interventions

The primary physical therapy intervention for this pathology is patient education. Patients must have a good understanding of the disease progress (may require a referral to a rheumatologist).

- Educate the patient about the proper, or "functional," posture before the spine becomes ankylosed. An exaggerated lumbar lordosis is required to facilitate a functional thoracic kyphosis and prevent the person from fusing in a posture in which the entire spine is in a kyphotic posture. This can be accomplished by instructing patients to sleep in a prone position and to use a pillow or towel roll behind their lumbar spine during all sitting activities.
- Gentle manipulations (grades I and II) for pain modulation at the non-ankylosed segments
- Segmental and global trunk stabilization and scapular stabilization exercises are mandatory to strengthen the muscles surrounding the spine.
- Stretch to maintain hip extension and shoulder flexion, as lumbar and thoracic extension may eventually be lost.

Scheuermann's Disease

This pathology is similar to HNP except the nucleus pulposus migrates either superior or inferior versus posterior or posterolateral. Scheuermann's disease is the result of a weakened vertebral end-plate. This weakness causes a crack and a breakdown in the weight-bearing ability of the vertebra. The nucleus pulposus then travels to the path of least resistance. Typically, patients with Scheuermann's disease do not have any radicular symptoms as the nerve roots are not involved.

Interventions

- Segmental and global stabilization exercises
- Stretching of tight muscles
- Posture education
- Joint manipulation may be used either for pain modulation or to improve ROM.[80] However, use caution with high-velocity techniques.

Rib Subluxation

The ribs articulate with the thoracic spine and move with all arm and thoracic activities. The place/location where the rib articulates with the thoracic spine is called a costovertebral joint. These joints can become sprained, or displaced, during twisting activities (unloading the trunk of a car or swinging a golf club), trauma (motor vehicle collision or fall), or following a period of prolonged sickness in which repetitive or aggressive coughing was involved. Radicular pain (intercostal nerve) may or may not be involved depending on the mechanism and severity of the injury. Muscle energy (ME) techniques may be used to correct either a posterior or anterior rib hypomobility.

Interventions VIDEO 15.1

- To correct a rib that has been forced and stuck in a posterior position, have the patient assume a sitting position. The therapist stands on the involved side. Place one hand lateral to the rib angle while resisting horizontal adduction (isometrically) with the other hand (Fig 15.10). During the isometric contraction, elicit an anteromedial force at the rib, attempting to improve movement. Hold the contraction and force for 3 to 5 seconds and repeat 3 to 5 times.
- To correct a rib that has been forced and stuck in an anterior position, have the patient assume a sitting position. Therapist stands on the uninvolved side. Place hand medial to the rib angle while resisting horizontal abduction with the other hand (Fig. 15.11). During the isometric contraction, elicit a posterolateral force at the rib attempting to improve movement.

FIGURE 15.10 ME technique to correct a posterior rib.

FIGURE 15.11 ME technique to correct an anterior rib.

The contraction and force are held for 3 to 5 seconds and repeated 3 to 5 times. A thorough assessment of the thoracic facet and intervertebral facet joints is also indicated.
